Given large geographic distribution and consistent point source of the trans-regional green tide in YS of China, containment measures are widely implemented throughout the coastline of the affected regions. Beside those measures (e.g., clearing algae mass from beaches and coastal waters manually, blocking drifting mats by arresting nets, etc.) to clean and protect the coastal facilities, recreation, and aquaculture along the downstream cities (Fig. 3), strategies to reduce the source biomass are also proposed and have been recently performed in Subei Shoal. These strategies range from pretreatments of the aquaculture facilities to reduce the epiphytic green macroalgae (e.g., antifouling coating, freezing, modified clay, etc.) to series of managements on aquaculture activities to reduce the initial floating biomass (e.g., removing the aquaculture facilities earlier without in situ cleaning, harvesting the initial floating biomass from the major transporting waterways etc., Wang et al. 2020). Apparently, more hygienic and sustainable marine aquaculture should be developed to abate the green tides and further protect the ecosystem in YS.

Phytoplankton bloom; Red tide

Definition

Harmful algal blooms (HABs) are a major ecological disaster in the ocean or freshwaters. From an ecological point of view, discoloration is mainly caused by the rapid growth or concentration of harmful or toxic microalgae, macroalgae, and cyanobacteria in water bodies under suitable environmental conditions. HAB species comprise two groups: those that are toxin producers, which can contaminate seafood or kill fish, and those that are high biomass producers, which, at high cellular concentrations, can have negative impacts on aquatic ecosystems, such as hypoxia and indiscriminate killing of marine organisms.

Introduction

HABs are natural ecological phenomenon, caused by rapid algal blooms or accumulation, which can have catastrophic economic or ecological consequences, such as mass mortality of marine animals, contamination of seafood, alteration of marine food webs, or deterioration of tourism (Yu et al. 2018). As shown in Fig. 1, the increased frequency and intensity of HAB worldwide in recent decades has been associated with anthropogenic eutrophication and climate change (Fu et al. 2012; Wells et al. 2015). Algal blooms can last from a few days to several months. Some microalgae are simple photosynthetic organisms that live in oceans and freshwater and can produce toxins that affect humans, fish, shellfish, marine mammals, and birds (Wells et al. 2015). There are different species of HABs, caused by different groups of algae, with different toxins (Granéli and Turner 2006). At the same time as algal blooms, especially during the termination phase, microorganisms may consume oxygen in the water column as they break down the extracellular organic matter of dead algae, resulting in the death of the fish. When some hypoxic zones cover large areas for long periods of time, they are called dead zones, and neither fish nor plants can survive in them. HABs are the end result of physical, chemical, and biological interactions, with excess nutri-

ents in the water considered one of the most important factors. Common nutrients are mainly nitrogen (nitrate, nitrite, ammonia, urea) and phosphate (Anderson et al. 2002).

Causative Organisms of HABs

Microalgae

Diatoms and Dinoflagellates

Diatoms and dinoflagellates are two distinct groups of phytoplankton that are found primarily in the marine environment and are the primary source of HAB species in marine and brackish water. They can form algal blooms and cause discoloration of the water column.

Some diatoms, such as *Pseudo-nitzschia* spp., can produce neurotoxins and domoic acid, which can affect the human nervous system and cause serious injury or death (Kim et al. 2015). Domoic acid (DA) can readily accumulate in the bodies of shellfish, sardines, and anchovies, which is then eaten by people, sea lions, otters, cetaceans, or birds. Due to high levels of DA detected in shellfish during the summer of 2015, the US government closed important shellfish fisheries on the US West Coast, including Washington, California, and Oregon (Ekstrom et al. 2020).

Many dinoflagellates produce a chemical that acts as a neurotoxin in other animals. For example, when dinoflagellates are ingested by shellfish, the chemical can accumulate to high enough levels in shellfish tissues to cause severe

neurological effects in humans, birds, or animals that ingest the shellfish. Some chemicals may affect the action of nerves and interfere with the movement of ions across cell membranes, thereby affecting muscle activity. The toxin saxitoxin, produced by *Alexandrium* and *Gonyaulax*, accumulates in shellfish. Eating such contaminated shellfish can lead to paralytic shellfish poisoning (PSP). Symptoms are typical of PSP, ranging from numbness of the lips and fingers to complete respiratory failure in mild cases to death in severe cases (Mee et al. 1986). Another toxin that accumulates in shellfish is brevetoxin, produced by the dinoflagellate *Karenia brevis* (Wang et al. 2019). Brevetoxin is unique in that when dinoflagellates end up in the surf zone, it turns into an aerosol that then blows onto the beach and causes irritation to the human respiratory tract. Diarrheal shellfish toxins (DTXs) are a class of polyether compounds produced by *Dinophysis* and *Prorocentrum*, among others, with at least eight congeners, the parent compound being okadaic acid (Hackett et al. 2009). Ciguatera is another form of dinoflagellate poisoning in the tropics and is caused by eating fish contaminated with the dinoflagellate *Gambierdiscus* toxin (Skinner et al. 2011; Smith et al. 2016).

Prymnesiophytes

Prymnesium parvum, commonly referred to as “golden algae,” is a single-celled microscopic (about 10 µm), flagellated algae with ichthyotoxic capabilities, and large blooms of *Prymnesium* spp. are often associated with fish kills

(Skovgaard and Hansen 2003). *P. parvum* is toxic not only to fish but also to organisms with gills, such as mussels and clams, and to the gill-breathing juvenile stage of frogs and other amphibians. This algae is found worldwide, with Europe reporting the highest number of large blooms of *P. parvum* (Edvardsen and Paasche 1998; Moestrup 1994).

Cyanobacteria

Cyanobacteria, also known as blue-green algae, are naturally occurring microscopic organisms found in all types of water. These single-celled organisms live in fresh, brackish (combined salt and freshwaters), and salt water. Toxicity by cyanobacteria has been reported since the late nineteenth century, primarily in freshwater environments (Carmichael et al. 1990). Some cyanobacteria can produce hazardous toxins, such as microcystins and hepatotoxins that target mammalian liver. HABs in freshwater lakes and rivers are a serious problem for drinking water and human health. Freshwater and cyanoHABs have major economic, social, and environmental impacts (Berdalet et al. 2017).

Macroalgae

Seaweed (*Ulva prolifera*) is a type of algae found all over the world that creates green tides (Li et al. 2020). The proliferation of *U. prolifera* has negative impact on local communities, aquaculture, and tourism, causing significant damage to the local ecosystem service and economic loss (Li et al. 2020; Zhang et al. 2014). The rapid growth of *U. prolifera*, on the other hand, makes it the strongest competitor for nutrients and light in the bloom area, thereby driving significant impacts on marine biodiversity and community structure (Li et al. 2020).

Sargassum is a genus of brown macroalgae (seaweed). The floating *Sargassum* bloom is called as the golden tides (Xing et al. 2017). The large recurring *Sargassum* beaching has caused serious environmental and economic problems (Wang and Hu 2017). As of June 2018, the Greater Atlantic Sargassum Belt, which extends 8,850 km, consists of more than 20 million tons of biomass. In another case, economic losses were

estimated at 50 million yuan (\$73 million) due to damage to seaweed farming in the Yellow Sea in China's Jiangsu Province in December 2016.

Causes

Among the causes of algal blooms, the following factors are generally considered to be responsible: pollution, eutrophication, anthropogenic impacts, and climate change.

With the progress and development of industry, especially with increasing urbanization and tourism activities, as well as growing coastal population, marine pollution is a growing problem on a global scale (APEC-OFWG 2019). There are three main types of pollution inputs to the ocean: direct discharge of waste into the oceans, runoff from rainwater into waters, and atmospheric releases of pollutants. Eighty percent of marine pollution comes from land-based sources. Air pollution is also a contributing factor, as it carries iron, carbonic acid, nitrogen, silicon, sulfur, pesticides, or dust particles into the oceans.

Eutrophication occurs when a body of water becomes overly enriched with minerals and nutrients, thus inducing excessive algae growth (Chislock et al. 2013). Nutrients enter the freshwater or marine environment in the form of surface runoff from agricultural pollution and urban runoff and from sewage treatment plants that lack nutrient control systems (Anderson et al. 2002; Heisler et al. 2008). Human activities have accelerated the rate and extent of eutrophication through point-source discharges and nonpoint loadings of limiting nutrients, such as nitrogen, phosphorus, and iron, into aquatic ecosystems.

Climate change stresses will affect marine plankton systems globally, and it is conceivable that the frequency and severity of HABs may increase. These climate change pressures will manifest as alterations in temperature, stratification, light, ocean acidification, precipitation-induced nutrient inputs, and grazing (Wells et al. 2015). Global warming, with climate change driving warmer waters, is also considered to be a key factor for algal blooms and making conditions

more favorable for algae growth in more regions and farther north (Lee et al. 2019).

Harmful Effects

Human Health

The main focus is marine, brackish, and freshwater red tide species that produce toxins that affect public health (Berdalet et al. 2017; Geohab 2001). The most virulent species are recorded in dinoflagellates, such as *Pyrodinium bahamense* var. *compressum* and several species of *Alexandrium*, which have significant effects at almost undetectable concentrations (10^2 – 10^3 cells l^{-1}). Fish and shellfish containing toxic phytoplankton are harmful to humans, and other fish, gastropods, crabs, etc. that accumulate algal toxins through the food chain are also toxic (Lewis et al. 1995; Shumway et al. 1995). Toxic syndromes caused by HABs include ciguatera fish poisoning, as well as paralytic, diarrhetic, neurotoxic, azaspiracid, and amnesic shellfish poisoning, primarily associated with the consumption of shellfish. Another concern is the respiratory problems associated with the migration of toxins from aerosols ashore under certain wind and wave conditions (Baden 1983). Although blue-green or other algae do not usually pose an immediate health threat, the toxins they produce are considered dangerous to humans, animals, birds, and fish. Symptoms of drinking toxic water can appear within hours of exposure. They may include nausea, vomiting, and diarrhea or cause headaches and gastrointestinal problems (Grattan et al. 2016). High concentrations of algal toxins can cause skin rashes and irritation to the eyes, nose, mouth, or throat (Grattan et al. 2016). If symptoms persist after 24 h, patients with suspected symptoms are advised to call a doctor.

Natural and Cultured Life Resources

Toxic algae indirectly affect the use of marine resources, while other HAB events directly affect wild and farmed fish and invertebrates, which are valuable seafood products. This is caused by algal toxins but also by mechanical blockages, gill damage, and hypoxia. HABs led

to massive fish kills (Grattan et al. 2016), in addition to the 23 million salmon farmed in Chile that died in 2016 due to toxic algae outbreaks (Gerhart 2017). To remove the dead fish, fish fit for consumption was made into fishmeal, and the rest was dumped 60 miles offshore to avoid any risk to human health (Gerhart 2017).

Recreational Activities and Tourism

Algal blooms can have significant negative impacts on tourism and recreational use of coastal areas. Tourism and recreation rely on relatively high water quality with no visible scum and noxious odors. On the Mediterranean coast, water discoloration and mucus caused by various nontoxic species occur frequently and often coincide with the tourist season, while in the Baltic Sea, during the warmest months, cyanobacterial blooms often hinder the recreational use of the sea (Geohab 2001).

Water Ecosystem Impacts

In addition to their effects on human health and seafood, toxins can move through ecosystems in a manner similar to carbon or nutrient flows, so their effects can be far-reaching. Negative impacts on viability, fecundity, recruitment, and growth are only just beginning to be recognized. Marine mammals have suffered morbidity and mortality from exposure to HAB toxins transmitted through the food web (Scholin et al. 2000). Mass mortality of seabirds, including brown pelicans and cormorants, has also been linked to the spread of diatoms, whose toxins are transferred through the consumption of contaminated pelagic fish (Work et al. 1993).

Clearly, the loss of noncommercial marine resources could also have serious consequences. High biomass, nontoxic HABs can have significant adverse effects on the entire ecosystems, such as reduced light intensity and damage to seagrass or coral reef communities following hypoxia. Severe attenuation of light by HABs results in reduced photosynthetic capacity and leaf biomass in eelgrass beds, leading to substantial loss of fish and shellfish nursery habitat. Oxygen depletion from the degradation of nontoxic blooms kills not only commercially important species but also

other plants and animals (Geohab 2001). When the algae eventually die, the microbes that break down the dead algae consume more oxygen, resulting in more fish dying or leaving the area. When oxygen is continually and heavily consumed, it can lead to hypoxic dead zones where neither fish nor plants can survive. Marine mammals have also been seriously harmed, with more than 50% of unnatural marine mammal deaths caused by HABs (Wilson et al. 2016). Many bottlenose dolphins died from Florida's red tide (Brown et al. 2018). Birds die after eating dead fish contaminated with toxic algae. Decomposing fish are poisoned when eaten by birds such as pelicans, gulls, cormorants, and possibly marine or land mammals (Grattan et al. 2016). The nervous systems of the dead birds have been examined, and due to the toxins, their nervous systems have failed (Starr et al. 2017). It has even been suggested that HABs are responsible for the death of the animals found in the fossil reservoir (Gramling 2017).

Other Economic Consequences

According to a 2016 report, the economic impact of HABs comes primarily from damage to human health, fisheries, tourism and recreation, and the cost of monitoring and managing areas where HABs occur (Ritzman et al. 2018). In addition to the damage to businesses, losses from human diseases include lost wages and impaired health. The imposition of fishing bans in areas where algal blooms are occurring has had a significant negative impact on fisheries, coupled with the consequent high fish mortality rates, increased prices due to shortages of available fish, and reduced demand for seafood due to concerns about toxin contamination (Avdelas et al. 2021). This has resulted in significant economic losses to the industry.

Potential Remedies

Chemical Treatment

Although some algacides are effective at killing algae, they are mostly used in small bodies of water. For large algal blooms, however, the

addition of algacides such as silver nitrate or copper sulfate may have worse effects, such as killing fish directly (Tsai 2016). So the negative effects may be worse than allowing the algae to die out naturally (Tsai 2016).

Microcystis is prevalent, using a new algacide formulation (by BlueGreen Water Technologies) that floats the granular product and slowly releases its active ingredient, sodium percarbonate, which releases hydrogen peroxide (H_2O_2) at the water's surface (Sinha et al. 2020). Therefore, effective concentrations are limited vertically to the water surface and spatially limited to cyanobacteria-rich areas. This provides a "safe haven" for aquatic organisms in untreated areas and avoids the adverse effects associated with the use of standard algacides.

Red Clay and Modified Clay

The flocculation of natural minerals is used to kill red tide organisms. The natural minerals are mainly clay minerals, supplemented by other minerals. They are characterized by abundant sources, low cost, low pollution, and high adsorption capacity. In Korea, natural red clay is often used to control serious red tide of *Cochlodinium polykrikoides* in order to reduce the risk to farmed economic fish. This has been proven to be the most effective and environmentally friendly mitigation strategy compared to other methods. In China, modified clays have been used several times to successfully treat HABs in oceans and lakes. For example, cyanobacteria bloom in Xuanwu Lake of Nanjing during the National Games and the site for sailing competition of Qingdao in 2008 Olympic Games. Compared to natural clays, modified clays are much more efficient at resisting red tide, but the cost will increase accordingly.

Monitoring and Predicting of HABs

A growing number of scientists agree on the urgent need to protect the public by predicting HABs. One way they hope to do that is through the use of sophisticated sensors to help warn of potential algal blooms (Binding et al. 2020). Water treatment facilities can also use the same type of sensors to help them prepare for higher toxicity (Brooks et al. 2017). In 2016, the

automatic early warning monitoring system was successfully tested and was shown for the first time to identify rapid algal growth and consequent oxygen depletion in the water column (Brooks et al. 2017).

It is widely believed that HABs have been increasing in frequency and geographic distribution worldwide. Over the past decade, HABs have appeared in all coastal areas around the world, and in some places new species have emerged that were not previously known to cause problems. The frequency of HABs is also thought to be increasing in freshwater systems (Schmale et al. 2019). The report recommends, among other remedial measures, the use of improved monitoring methods in an effort to increase predictability and the testing of new potential methods for controlling HABs (Schmale et al. 2019).

Reducing Chemical Runoff

Nitrates and phosphorus in fertilizers can lead to algal blooms when they flow into lakes and rivers after heavy rains. Changes in farming practices, such as targeted use of fertilizers only at the right time, have been suggested to reduce potential runoff (Hayder et al. 2019). Drip irrigation is a successfully used method that does not spread the fertilizer widely over the field but rather drips the plant roots through a network of pipes and emitters, leaving no trace of the fertilizer being washed away (Çetin and Akalp 2019).

Definition

The *heave plate* is a damping device, usually attached to the submerged end of Spar-like floating platforms. Its primary function is to suppress the heave motion responses of the floating

structures and also shift the natural heave period further away from the typical incident wave by increasing the *added mass* and *viscous damping* of the floating platform.

Scientific Fundamentals

Introduction

After over 30 years of development, the Spar platform has become the most cost-effective floating platform for offshore oil and gas production in deep and/or ultra-deep water. As a deep draft floating oil platform, the Spar platform consists of a large diameter single vertical cylinder. Due to its deep draft, the Spar platform has excellent heave performance. After the first Spar platform (Neptune Spar) was designed by Kerr McGee in 1996, three primary types of Spar platform have been formed, including the Classic Spar, Truss Spar, and Cell Spar platforms as shown in Fig. 1.

The Classic Spar platform almost relies on the deep draft to obtain an excellent heave performance. However, the cost sharply grows with the increase of the draft. Thus the Truss Spar platform had been widely used to overcome the shortcomings. It has a shorter hard cylindrical tank than the Classic Spar and truss structure connected to the bottom of the hard tank (see Figs. 1 and 2). The truss structure consists of four sizable orthogonal legs with X-braces and a small keel (or soft tank), which houses the heavy ballasting material. Generally, the truss structure can't supply adequately the added mass and viscous damping. Although the natural period of heave response of a Spar platform is about 20s to 30s which is far away from the wave period (Subbulakshmi et al. 2015), heave resonant oscillations may occur due to long period waves. Thus, additional damping devices and active damping systems are introduced to reduce the heave motion. The most typical device is the heave plate. As shown in Figs. 1 and 2, a heave plate is a thin plate structure to reduce the heave response by increasing the added mass and damping of Spar platform. The circular, square, and hexagonal are the three primary shapes of the heave plate.

Heave Plate, Fig. 1 Typical types of the Spar platform. (www.ourworldofenergy.com)

Heave Plate, Fig. 2 Typical structure of the Truss Spar platform

Similar to the Truss Spar platform, the Cell Spar platform also designs the heave plate.

Hydrodynamic Performance

In general, the motion response of a floating platform should be small enough to enable the operation of rigid risers. Further minimizing the heave response and maximizing the natural heave period of Spar platform, respectively, are two key processes to reduce the heave motion. The Keulegan-Carpenter number (KC) and frequency parameters (β) are the two

nondimensional characteristic parameters representing hydrodynamic response and heave period, respectively (Tao and Thiagarajan 2003a).

$$KC = 2\pi x/D \quad (1)$$

$$\beta = D^2 f/\nu \quad (2)$$

Note that D is the diameter of the cylinder (side length when the Spar platform hull is square), x and f are the amplitude and frequency of the oscillation, and ν is the kinematic viscosity of the fluid, respectively. The natural heave period is formulated by $T = 2\pi/f = 2hC_m/g$, where h is the Spar draft and C_m is the added mass coefficient. The coefficient C_m and viscous damping coefficient C_d in the Morison equation are often used to describe the hydrodynamic characteristics.

$$(M + \rho \nabla C_m) \ddot{x} + 1/2 \rho A C_d |\dot{x}| \dot{x} = F \quad (3)$$

Note that M is the mass of the Spar platform, ρ is the density of water, ∇ is the volume displacement, A is the projection area of the structure, $\dot{x}$ and $\ddot{x}$ are the speed and acceleration of the structure, and F is the force on the system, respectively (Sarpkaya et al. 1981). On one hand, the heave plate increases the added mass and mass coefficient C_m . It increases the heave period T and decreases the value of frequency parameter. On the other hand, increasing the viscous

damping C_d also can reduce the heave response x of the Spar platform based on Eq. (3). In short, the heave plate increases the added mass and viscous damping to gain an excellent heave performance.

The Influencing Factors of Heave Plate to Spar Hydrodynamic Performance

The principal factors of heave plate affecting the hydrodynamic performance of the Spar platform are listed in Table 1.

The Size of Heave Plates

Downie et al. (2000) obtained the damping ratio ξ and natural period T of solid and perforated heave plates which have the side length of 0.395 and 0.295 m as showed in Table 2. It is indicated that the larger heave plate makes the bigger damping

ratio and the longer natural period. Thus the heave plate should be as large as possible to achieve a superior movement stability.

The Number of Heave Plates

Due to the shielding effects between the heave plates, the increase rate of the added mass is usually lower than the growth rate of the number of the heave plate. Thus, the average added mass of each heave plate will decrease based on these effects. Using the numerical and experimental data, many researchers studied the heave motion of the Spar platform with single and two heave plates (Downie et al. 2000; Tao and Thiagarajan 2003b; Tao and Cai 2004; Tao et al. 2007; Sudhakar and Nallayarasu 2013; Subbulakshmi et al. 2015). As shown in Table 3, two or three heave plates are usually installed for the most Truss and Cell Spar platforms in practice.

The Spacing of Heave Plates

From structural design, the angle of the X-braces is usually about 45° . The leg spacing of legs L1 is equal to the spacing of heave plates H ($L1 = H$) and the standard value of L1 is $0.707D$ ($L1 = 0.707D$). The width of heave plate L is usually extended to the diameter of hard tank D ($L = D$). The typical spacing of heave plates H is $0.70L-0.75L$, and the added mass of each heave plate is 85–95% of the single heave plate. The efficiency of the heave plate is about 90%. It is concluded that reducing the spacing of heave plates will reduce its effectiveness. But for resistance, the effect of spacing is not significant (Prisilin et al. 1998). Ji et al. (2003) conducted the experiment with the triangular heave plate using the forced oscillation method. The vicious damping coefficient C_d obtains the maximum when $H = 1.5L$, and the added mass coefficient C_m obtains the maximum when $H = 1.0L$. Shen et al. (2011) simulated the square heave plate, and the result suggested that the added mass coefficient C_m obtains the maximum (about 90% of the added mass coefficient of the single heave plate) when $H > 1.5L$. On the other hand, the damping coefficient C_d would not increase anymore with the spacing increasing when $H > 1.5L$ (Fig. 3).

H

Heave Plate, Fig. 3 Heave plate on the Truss Spar platform (Ji et al. 2003)

The Shape of Heave Plates

The circular, square, and hexagonal are the three primary shapes of the heave plate. With the same area and thickness of abovementioned three plates, the circular heave plate has the maximum damping coefficient C_d , and the hexagonal

has the maximum added mass coefficient C_m (Wu et al. 2012).

The Thickness of Heave Plates

The main damping of heave plate is caused by the vortex shedding at the thin edge. When the thickness t is small, the strong interaction between the vortices appearing at the upper and lower edges appeared. He (2003) found that the damping effects are significantly reduced when $t > 1/50L$. Experimental study also demonstrates that the added mass decreases as the aspect ratio t/L increases, and with aspect ratio t/L (exceeds $1/50$) increasing, the viscous damping coefficient greatly decreased (Liu et al. 2012).

The Porosity of Heave Plates

Opening in the heave plate increases the perimeter in contact with the water and creates more vortex shedding to enhance the damping effects. Numerical and experimental studies show that the damping of heave plate increases first and then decreases with the increase of the rate of opening (Wu et al. 2012; Zhang et al. 2006). However, the added mass decreased, and the influence of the rate of opening is remarkable at a small KC (Wu et al. 2012). The maximal damping coefficient C_d is acquired at 10% porosity. Further the opening should be as small as possible to obtain a larger opening perimeter (Zhang et al. 2006).

Besides, the added mass and viscous damping coefficient do not significantly increased with the diameter of opening decreasing and the number of the openings increasing at the same porosity (Wu et al. 2012).

The KC Number

KC reflects the impact of the amplitude to the hydrodynamic characteristics of heave plates. Liu et al. (2012) studied the Spar model with three heave plates in the experiment. The added mass coefficient C_m increased as KC changed from 0.2 to 1.3. The viscous damping coefficient C_d decreased significantly when KC is changed from 0.2 to 0.4. But it decreased slowly with the varying of KC from 0.4 to 1.3.

The Load of Heave Plate

The shear deformation of the truss caused deformation and stress of the heave plate. In key regions, the stress caused by shear deformation could reach about 50% of the total stress (Gao and Liu 2007). The solution is to add displacement to the leg on the local finite element model of the heave plate and then superimpose the analysis results on the basic of the previous analysis. Besides, the Spar platform floats on its buoyancy and is towed by a tug in the process of wet tow. About one-third of heave plates are submerged in water, and the load distribution is different from that when it is in place.

Conclusions

As a vital component of the Spar, the heave plate increases the added mass and extra viscous damping of the marine structure to reduce the heave motion. It's an economical and practical strategy to improve the stability of the structures by installing a heave plate. Further research on its hydrodynamic performance and structural optimum design is still significant to ensure the safe, reliable, and high-efficiency operation of the Spar platform.

Definition

High-performance ship is a general name of a ship with a significant advantage over a conventional draining-type ship to achieve high speed, good navigability, and economical efficiency.

Scientific Fundamentals

Development History

High-performance ships are completely or partially out of the water during high-speed navigation, to reduce water resistance, especially wave resistance, and greatly reduce the swaying of the hull caused by waves, which can effectively improve the ship's speed and wave resistance. When the ship is at high speed, the buoyancy of the ship will not be used as the main factor to support the weight of the ship (Zhao and Xie 2009).

A series of new variations of high-performance ships have been developed in the last half century, including improved planing craft from the 1940s, hydrofoils from the 1950s, air-cushion vehicles and surface effect ships from the 1960s, small water plane area twin hull craft from the 1970s, high-speed catamarans from the 1980s, wave piercing craft from the 1990s, high-speed trimarans in the first decade of the twenty-first century, and wing in ground effect craft from 1970s to the present. These various concepts and the hybrids that we will describe form an interacting group of vehicle concepts (Liang and Bliault 2012). The following are the main types of high-performance ships, which are briefly introduced.

Key Technology

High-performance ships are a new type of ship developed from the 1930s of last century. The starting point of the exploration, research, and development of high-performance ships is how to make use of the supporting action of the water body by using the different supporting methods and the fluid mechanics principle with the conventional ship and at the same time get rid of the friction resistance of the surface water of the hull and the free surface wave resistance.

The high-speed navigation of the ship is realized. After decades of research and development, the research, design, construction, and operation technology of high-performance ships have become increasingly mature. The industry has developed various types of high-performance ships, which meet the special requirements of shipping and military to all kinds of shipping and operation of ships. As a young branch of ancient water transportation, high-performance ships are playing a more and more significant role in the field of civil and national defense (Liang and Bliault 2012).

Key Applications

Planing Craft

The concept of planing ship was recognized in the late nineteenth century; the first practical application of the concept can be traced to the development of seaplane hulls during the beginning of the twentieth century. Planing ships have important commercial applications, such as in offshore supply operations for the oil industry; high-speed support is becoming increasingly important as oil production operations move into deeper water farther offshore. Militarily, the role of special forces is increasing, and speed is necessary for effective littoral zone operations. The military high-speed sealift effort has recently renewed its interest in the development of smaller, high-speed

ships, of which planing or semi-planing hull forms are a principal alternative.

There are two basic types of ship hulls, displacement and planing, respectively. Ships with displacement hulls move through the water by pushing the water aside and are designed to cut through the water with little propulsion. Ships with planing hulls are designed to rise up and glide on top of the water when enough power is supplied. These ships may operate like displacement hulls when at rest or at slow speeds but climb toward the surface of the water as they move faster.

A planing craft is a high-powered watercraft that develops the lift force that supports its weight primarily through hydrodynamic water pressure. In order to develop sufficient dynamic supporting lift, the speed of the planing craft must be high relative to its size, and the surfaces of the hull must be properly configured. The proper hull surface configuration is generally a shallow V-section with some variation both longitudinally and transversely. The planing ship is typically run with a bow-up trim angle of a few degrees (Vorus 2017). This trim results in development of high pressure on the hull bottom, which pushes the ship upward toward the water surface, thereby reducing its immersed surface area and, consequently, the ship resistance relative to the case of full displacement (Fig. 1) (Sakaki et al. 2017).

The planning ship has high speed, small tonnage, and flexible manipulation, but the skiing

High-Performance Ship,

Fig. 1 Planing craft (http://www.boated.com/washington/studyGuide/Planing-Hulls/10105001_700060590)

waves have great impact on the hull, and the stall in the wind and waves is great, so the skiing boat is not suitable for sailing in the large wind and waves. The sewerage of the planing ship is generally within 200 t, and the speed can reach 40–50 knots.

Hovercraft

A hovercraft, also known as an air-cushion vehicle or ACV, is a craft capable of traveling over land, water, mud, or ice and other surfaces both at speed and when stationary. Hovercrafts are hybrid vessels operated by a pilot as an aircraft rather than a captain as a marine vessel. A hovercraft is a high-speed ship that uses the principle of surface effect to form air cushion between the hull and the support surface (surface or ground) to make the whole or part of the ship sail out of the support surface, depending on the principle of surface effect. The speed of a hovercraft is usually 30–80 knots, and that of a military hovercraft can reach 90–100 knots.

Hovercraft use blowers to produce a large volume of air below the hull that is slightly above atmospheric pressure. The pressure difference between the higher-pressure air below the hull and lower-pressure ambient air above it produces lift, which causes the hull to float above the running surface. For stability reasons, the air is typically blown through slots or holes around the

outside of a disk- or oval-shaped platform, giving most hovercraft a characteristic rounded rectangle shape. Typically, this cushion is contained within a flexible “skirt,” which allows the vehicle to travel over small obstructions without damage. Vehicles designed travel close to but above ground or water. These vehicles are supported in various ways. Some of them have a specially designed wing that will lift them just off the surface over which they travel when they have reached a sufficient horizontal speed (the ground effect). Hovercrafts are usually supported by fans that force air down under the vehicle to create lift. Air propellers, water propellers, or water jets usually provide forward propulsion. Air-cushion vehicles can attain higher speeds than can either ships or most land vehicles and use much less power than helicopters of the same weight (Amit 2015) (Fig. 2).

Hovercraft has the following characteristics:

1. Low resistance and high speed. The effect of air cushion is free from the obstacle of the increase of water resistance exponentially with the speed of the conventional sewerage, which provides a basic condition for increasing the ship's speed.
2. Amphibious. The full hovercraft has a unique amphibious nature, which can pass through shallow water, swamps, ice and snow, beach

High-Performance Ship,
Fig. 2 Air-cushion vehicle
(<http://military.wikia.com/wiki/hovercraft>)

and land, and so on. It has good navigability, and it can be landed and cross barrier without terminal facilities.

3. Large deck area and storage capacity can be set up. Because most of the hull of the hovercraft is off the water, the volume is increased, and there is no excessive resistance. Therefore, a large deck area and storage capacity can be set up as required, without causing too much resistance.
4. Good overloading ability. Unlike hydrofoil and gliding ships, the hovercraft is a cushion lift by the lift system separated from the propulsion system. Overloading only causes a slow decline in the speed of the aircraft, unlike the skidding ship or the hydrofoil ship that is unable to slide or lead to the speed of the flight.

Hovercraft has the advantage of being applied all-weather. It can be used in shallow water rapids, swampy areas, shallow deepwater beaches, and icicles. In particular, it is driven through harsh waterways and roads, which shows the unparalleled advantages of ordinary ships. The resistance of the hovercraft is very small during the driving process, and the speed is fast. The disadvantages include poor stability, difficulty in handling, high stall speed and poor wind resistance, and high noise.

Hydrofoil Craft

As early as 1905, the Italian inventor invented the first hydrofoil and carried out trial tests with a speed of 36 kn. Hydrofoil boats have received much attention since then. Then in 1918, American Bell improved the hydrofoil craft and built a hydrofoil craft that could theoretically reach a speed of 60 kn and successfully sailed. In 1935, Germany developed and cut a type V hydrofoil with a speed of 30 kn. The Soviet Union has developed rapidly in the construction of hydrofoil craft. It has built 12 types of hydrofoil boats and put them into use since 1957. Most of them are self-stabilizing and self-settling controlled hydrofoils, operating at speeds up to 37 kn. The United States is also one of the major hydrofoil developing countries. Its research and

development of fully flooded controlled hydrofoil passenger boats use water jet propulsion devices. In 2005, the China Ship Science Research Center designed and built China's first mixed hydrofoil catamaran, which greatly reduced the resistance and roll response to navigation in waves.

Hydrofoil craft is a ship with submerged hydrofoils under the hull. At high speed, the weight of the ship is entirely supported by the lift force generated by the water to the hydrofoil, so that the hull is all away from the water surface, reducing the resistance of the water, so it can reach a higher speed. The principle of the action of a hydrofoil is similar to the wing of an aircraft. Some speed ships only have hydrofoil in the capital, leaving the front part off the water and the rear still sliding on the water.

Hydrofoil is the wing that works in water or cuts the surface of the water. It is the basic component of hydrofoil. It moves in water, like airplane wings moving in the air, which gives rise to certain lift. Because the density of water is about 800 times that of air density, the diameter of hydrofoil is much smaller than that of the wing under the same lift. The hydrofoil based on the lift force of the hydrofoil has smaller resistance than the planing ship, little wave propagation, and little influence on wave interference, so it has good rapidity and seaworthiness.

When used as a lifting element on a hydrofoil ship, this upward force lifts the body of the vessel, decreasing drag and increasing speed. The lifting force eventually balances with the weight of the craft, reaching a point where the hydrofoil no longer lifts out of the water but remains in equilibrium (Ling et al. 2011). Since wave resistance and other impeding forces such as various types of drag on the hull are eliminated as the hull lifts clear, turbulence and drag act increasingly on the much smaller surface area of the hydrofoil, and decreasingly on the hull, creating a marked increase in speed (Fig. 3).

Early hydrofoils used V-shaped foils. Hydrofoils of this type are known as "surface-piercing" since portions of the V-shape hydrofoils rise above the water surface when foilborne. Some modern hydrofoils use fully submerged inverted T-shape foils. Fully submerged hydrofoils are less

subject to the effects of wave action and, therefore, more stable at sea and more comfortable for crew and passengers. This type of configuration, however, is not self-stabilizing. The angle of attack on the hydrofoils must be adjusted continuously to changing conditions, a control process

performed by sensors, a computer, and active surfaces (Fig. 4). The main advantages of hydrofoil craft are low resistance at high speeds. When the hydrofoil is in the wing state, the hull is lifted by the hydrofoil, and only the hydrofoil, the rudder, and the shaft

system are used for the underwater components. Therefore, the water resistance has been greatly reduced, and the speed has been greatly improved. The existing hydrofoil can reach a maximum speed of 70 knots; the wave resistance is good. As the hull is lifted off the water surface in the wing state, the disturbance of the wave to the hydrofoil is reduced, so the swaying motion of the hydrofoil in the wind and waves is reduced, and its wave resistance is greatly improved. The wave of high-speed sailing is small. Since only the hydrofoil, rudder, and other components are in the water during the wing state, the rising waves are very small. Therefore, hydrofoil craft is very suitable for inland shipping, which can greatly reduce the damage of the wave on the embankment; physical field radiation is low. When the hydrofoil is in the wing state, the physical field radiation of the hull will be weakened due to the hull being separated from the water surface. In particular, the sound radiation will be greatly reduced. The low-physics radiation characteristics of the hydrofoil craft help to increase the stealth of the ship and reduce the risk of underwater attack; the maneuverability is good. When the hydrofoil is under wing flight, it uses the combined action of the flap and the rudder to make the hull produce a safe inward rotation and thus has a good gyration.

The main disadvantages of hydrofoil craft are hydrofoil under the hull, not suitable for shallow waterways; hydrofoil width is often greater than the width of the ship; berthing docks is inconvenient; high-speed internal combustion engines or gas turbines are often used to reduce the weight of the main engine; and the service life is short. The demand for fuel is high and the economy is poor. Due to the limitations of hydrofoil lift and structural strength, there are still technical difficulties in manufacturing large-scale hydrofoil vessels or further increasing the speed. The buoyancy provided by the hydrofoil is squared with the length, but the weight of the vessel is related to the length of the vessel (square/cubic law). Therefore, it is difficult to manufacture larger hydrofoil vessels. To further increase the speed, the problem that the hydrofoils will generate bubbles at high speeds also needs to be solved. In addition, the structure

and control of the full-immersion hydrofoil are relatively complicated, which also increases the cost. The use of fuel gas engines for hydrofoil vessels is also one of the considerations for commercial operation.

Wing in Ground Effect Vehicles

Wing in ground effect vehicles (WIG) are an emerging technology that provide a surface transport utility that is between aircraft and existing marine craft, in terms of speed, cost (capital and running), and load carrying capacity (Klaus and Hanno 2003). With a cruising speed of circa more than 90 knots, they are faster than almost all other seagoing craft, and over short/medium distances, they provide journey times comparable with helicopter and aircraft. Yet they can be built, certified, and operated as ships. Skimming above the water but without water contact provides efficiency and long endurance, with no sea motion fatigue and no wake and having natural stealth. Such vehicles are of potential use in both civil and paramilitary fields (Fig. 5).

A WIG vehicle is a dynamic hovercraft. Unlike a conventional hovercraft that generates a static cushion which is dragged around within a skirt, the WIG generates a dynamic cushion between itself and the surface below it by virtue of its own forward passage. The WIG utilizes wing-in-ground effect, a phenomenon that relates to the airflow around a wing when it flies in close proximity to a surface, wherein the presence of the surface distorts the downwash from the wing and inhibits the formation of vortices. This results in two beneficial effects (Moore et al. 2002). There is a pressure increase on the lower surface of the wing due to the conversion of the dynamic pressure of the forward motion to static pressure, which results in a substantial increase in lift. At the same time, there is a substantial reduction in (lift-induced) drag because the vortices and downwash are less, so there is less energy stored in them. The combined effects lead to a higher lift/drag ratio for a wing in ground effect than could be achieved in free flight and hence higher efficiency. Indeed, heavy seabirds use this ground effect to save their energy on long-distance flights. However, birds have a natural automatic

High-Performance Ship,

 effect vehicles (http://www.savorlife.com/main_travel.htm)

H

height and longitudinal stabilization system. Dr. Lippisch regarded aircraft as “frozen birds” that needed special methods for self-stabilization. He solved this by using a reversed Delta wing, flying in ground effect, in combination with a high T-Tail, which flies out of ground effect. This configuration guarantees a safe stability at all heights from the surface. The ground effect gets stronger as the surface is approached and efficient cruise height is a balance between wave clearance and the optimum power efficiency and generally equates to a cruise height of equivalent to 10% of wing span.

High cruise speed and transportation efficiency are the main advantages. However, poor maneuverability and high accident risk are the main disadvantages.

Multihull Vessels

A multihull is a ship with more than one hull. Multihull ships (vessels, craft, ships) include multiple types, sizes, and applications. Hulls range from two to five, of uniform or diverse types and arrangements. Catamarans are the most common type, with two symmetric hulls. They are used as racing, sailing, tourist, and fishing ships. A trimaran is a multihulled vessel, consisting of one long main hull and two shorter outriggers, also called wing hulls, located on both sides of the main hull. The outriggers provide the trimaran with excellent stability and seakeeping characteristics (Kang et al. 2001). A trimaran can be either

wind driven as shown or mechanically driven. Another unique feature of the trimaran design is the small ratio of width to length. Trimarans are typically designed with very long and slender hull shapes in order to decrease the wave-making resistance of the ship. The main hull and outriggers can also be arranged so that the waves produced by the ship destructively interfere, producing smaller waves and thereby losing less energy to wave-making resistance (Xu and Zou 2001).

Wave-making resistance is classified as the drag force on the trimaran which is created by the loss of energy to the formation of waves. The excellent seakeeping performance and the lower resistance at high speeds make the trimaran design appropriate for high-speed travel applications. Currently, trimarans are being used for business, recreation, and military applications because of their particular advantages over monohull ship designs. Trimarans have a much smaller draft than most ships, which allows them to access areas inaccessible to ships of similar size; draft is defined as the distance which a ship extends below the water surface. Ferries and sail ships have been designed using the trimaran configuration in order to provide the high speeds necessary for commercial transportation and racing. The trimaran design is also favorable for military and research applications due to the large open deck space available for equipment (Figs. 6 and 7).

**High-Performance Ship,****Fig. 7** A trimaran (<https://wordlesstech.com/adastra-trimaran-superyacht/>)**SWATH**

A small waterplane area twin hull, better known by the acronym SWATH, is a twin-hull ship design that minimizes hull cross section area at the sea's surface. Minimizing the ship's volume near the surface area of the sea, where wave energy is located, maximizes a vessel's stability, even in high seas and at high speeds. The bulk of the displacement necessary to keep the ship afloat is located beneath the waves, where it is less affected by wave action. Wave excitation drops exponentially as depth increases (deeply submerged submarines are normally not affected by wave action at all). Placing the majority of a ship's

displacement under the waves is similar in concept to creating a ship that rides atop twin submarines (Misra 2015) (Fig. 8).

A narrow waterline distinguishes a SWATH ship from a conventional catamaran. The twin-hull design provides a stable platform and large, broad decks. Compared with conventional catamarans, SWATH vessels have more surface drag, but less wave drag; they are less susceptible to wave motion but more sensitive to payload, which affects draft. Additionally, SWATH vessels cannot operate in planing or semi-planing modes and thus gain no drag reduction when operating at speeds normally associated with such modes,

High-Performance Ship,

require a complex control system, have a deeper draft, and have higher maintenance requirements. The design of SWATH vessels is also considerably more complex due to the structural complexities inherent to the design (Busch 1990).

Introduction

Nonlinear equations are difficult to solve, especially analytically. Perturbation techniques (Dyke 1975; Hinch 1991; Murdock 1991; Nayfeh 1973) are widely applied in science and engineering, and do great contribution to help us understand many nonlinear phenomena. However, it is well known that perturbation techniques are essentially based on the existence of small or large parameters or variables called perturbation quantity. Briefly speaking, perturbation techniques use perturbation quantities to transfer a nonlinear problem into an infinite number of linear subproblems and then approximate it by the sum of solutions of the first several subproblems. The existence of perturbation quantities is obviously a cornerstone of perturbation techniques; however, it is the perturbation quantity that brings perturbation techniques some serious restrictions. Firstly, it is impossible that every nonlinear problem contains such a perturbation quantity. This is an obvious restriction of perturbation techniques. Secondly, analytic approximations of nonlinear problems often break down as nonlinearity becomes strong, and thus perturbation approximations are valid only for nonlinear problems with weak nonlinearity.

To overcome the restrictions of perturbation techniques, some traditional nonperturbation methods are developed, such as Lyapunov's artificial small parameter method (Lyapunov 1992), the δ -expansion method (Awrejcewicz et al. 1998; Karmishin et al. 1990), Adomian's decomposition method (1976, 1991, 1994), and so on. In principle, all of these methods are based

on a so-called artificial parameter, and approximation solutions are expanded into series of such kind of artificial parameter. This artificial parameter is often used in such a way that one can get approximation solutions efficiently for a given nonlinear equation. Compared with perturbation techniques, this is indeed a great progress. However, like perturbation techniques, both the Lyapunov's artificial small parameter method and the δ -expansion method themselves do not provide us with a convenient way to adjust convergence region and rate of approximation series. And Adomian's decomposition method has also some restrictions. Approximate solutions given by Adomian's decomposition method often contain polynomials. In general, convergence regions of power series are small, thus acceleration techniques are often needed to enlarge convergence regions. This is mainly due to the fact that power series is often not an efficient set of base functions to approximate a nonlinear problem, but unfortunately Adomian's decomposition method does not provide us with freedom to use different base functions. Generally speaking, all traditional non-perturbation methods, such as Lyapunov's artificial small parameter method, the δ -expansion method, and Adomian's decomposition method, cannot guarantee the convergence of approximation series.

In summary, both of the perturbation techniques and the non-perturbative methods talked above themselves cannot provide us with a simple way to adjust or control the convergence region and rate of given approximate series. The efficiency to approximate a nonlinear problem has not been taken into enough account, and therefore it is necessary to develop some new analytic methods have the following advantages.

- It is valid even if a given nonlinear problem does not contain any small/large parameters at all.
- It can be employed to efficiently approximate a nonlinear problem by choosing different sets of base functions.
- It itself can provide us with a convenient way to adjust and control the convergence region and rate of approximation series when necessary.

In theory, the analytical approximation method with the above advantages should not be unique. In this entry, we introduce an analytical approximation method based on the basic concept of homotopy topology theory, namely homotopy analysis method (HAM) (Liao 1992, 1997a, b, 1999, 2003, 2004, 2009, 2010a, b, 2011a, b; Liao and Tan 2007; Liao and Zhao 2016). Since its introduction, the method has been gradually developed and continuously improved in application. It has initially formed a relatively complete theoretical system, and has been successfully applied in many fields of science and engineering, and even found new solutions which are not found by other analytical methods and numerical methods of some nonlinear problems.

The Basic Idea of HAM

In 1992, Liao (1992) proposed a preliminary framework for homotopy analysis method (HAM) based on the homotopy theory in topological theory. In order to ensure the convergence of the series solution, Liao (1997a, b) further generalized the zero-order deformation equation by introducing a nonzero auxiliary parameter $\hbar$ in it. This nonzero auxiliary parameter $\hbar$ which is called the “convergence-control parameter” is replaced by c_0 to avoid confusion of $\hbar$ meaning in the later researches. The introduction of the “convergence-control parameter” $\hbar$ (c_0) is a milestone for the HAM. And then, in 2003, Liao (2003) introduced a nonzero auxiliary function $H(\mathbf{r}, t)$ into the so-called zero-order deformation equation which makes the zero-order deformation equation more general. The basic ideas of HAM are explained below.

Deformation Equations

For a nonlinear equation,

$$\mathcal{N}[u, (\mathbf{r}, t)] = f(\mathbf{r}, t). \quad (1)$$

In the framework of homotopy analysis method (HAM) which was proposed by using the homotopy, a basic concept in topology, we first construct a family of solution $\varphi(\mathbf{r}, t; q)$ in

$q \in [0, 1]$ by means of the so-called zeroth-order deformation equation:

$$(1 - q)\mathcal{L}[\varphi(\mathbf{r}, t; q) - u_0(\mathbf{r}, t)] = c_0 q H(\mathbf{r}, t) \mathcal{N}[\varphi(\mathbf{r}, t; q) - f(\mathbf{r}, t)], \quad (2)$$

where $\mathcal{L}$ is an auxiliary linear operator with the property $\mathcal{L}[0] = 0$, $\mathcal{N}$ is the nonlinear operator related to the original Equation (1), $q \in [0, 1]$ is the embedding parameter in topology (called the homotopy parameter), $\varphi(\mathbf{r}, t; q)$ is the solution of (2) for $q \in [0, 1]$, $u_0(\mathbf{r}, t)$ is an initial guess, $c_0 \neq 0$ is the so-called “convergence-control parameter,” and $H(\mathbf{r}, t)$ is an auxiliary function that is nonzero almost everywhere, respectively. Note that, in the framework of HAM, we have great freedom to choose the auxiliary linear operator $\mathcal{L}$, the initial guess $u_0(\mathbf{r}, t)$, the auxiliary function $H(\mathbf{r}, t)$, and the value of the “convergence-control parameter” c_0 .

When $q = 0$, due to the property $\mathcal{L}[0] = 0$, from (2), we have the solution

$$\varphi(\mathbf{r}, t; 0) = u_0(\mathbf{r}, t). \quad (3)$$

When $q = 1$, since $c_0 \neq 0$ and $H(\mathbf{r}, t) \neq 0$ almost everywhere, Eq. (2) is equivalent to the original nonlinear Equation (1) so that we have

$$\varphi(\mathbf{r}, t; 1) = u(\mathbf{r}, t), \quad (4)$$

where $u(\mathbf{r}, t)$ is the solution of the original Equation (1). Thus, as the homotopy parameter q increases from 0 to 1, the solution $\varphi(\mathbf{r}, t; q)$ of Eq. (2) varies (or deforms) continuously from the initial guess $u_0(\mathbf{r}, t)$ to the solution $u(\mathbf{r}, t)$ of the original Equation (13). For this sake, Eq. (2) is called the zeroth-order deformation equation.

Here, it must be emphasized once again that we have great freedom and flexibility to choose the auxiliary linear operator $\mathcal{L}$, the auxiliary function $H(\mathbf{r}, t)$, and especially the value of the convergence control parameter c_0 in the zeroth-order deformation Equation (2). In other words, the solution $\varphi(\mathbf{r}, t; q)$ of the zeroth-order deformation Equation (2) is also dependent upon all of the auxiliary linear operator $\mathcal{L}$, the auxiliary function $H(\mathbf{r}, t)$, and the convergence-control parameter c_0 as a whole, even though they have no physical meanings. Assume that $\mathcal{L}$, $H(\mathbf{r}, t)$, and c_0 are

properly chosen so that the solution $\varphi(\mathbf{r}, t; q)$ of the zeroth-order deformation Equation (2) always exists for $q \in (0, 1)$ and besides it is analytic at $q = 0$, and that the Maclaurin series of $\varphi(\mathbf{r}, t; q)$ with respect to q , i.e.,

$$\varphi(\mathbf{r}, t; q) = u_0(\mathbf{r}, t) + \sum_{m=1}^{+\infty} u_m(\mathbf{r}, t) q^m, \quad (5)$$

converges at $q = 1$. Then, due to (4), we have the approximation series

$$u(\mathbf{r}, t) = u_0(\mathbf{r}, t) + \sum_{m=1}^{+\infty} u_m(\mathbf{r}, t). \quad (6)$$

Substituting the series (5) into the zeroth-order deformation Equation (2) and equating the like-power of q , we have the high-order approximation equations for $u_m(\mathbf{r}, t)$, called the m th-order deformation equation

$$\begin{aligned} \mathcal{L}[u_m(\mathbf{r}, t) - \chi_m u_{m-1}(\mathbf{r}, t)] \\ = c_0 H(\mathbf{r}, t) R_{m-1}(\mathbf{r}, t) \end{aligned} \quad (7)$$

Where

$$R_k(\mathbf{r}, t) = \frac{1}{k!} \left\{ \frac{\partial^k}{\partial q^k} \left(\mathcal{N} \left[\sum_{n=0}^{+\infty} u_n(\mathbf{r}, t) q^n \right] - f(\mathbf{r}, t) \right) \right\} \Big|_{q=0}, \quad (8)$$

with the definition

$$\chi_k = \begin{cases} 0, & \text{when } k \leq 1 \\ 1, & \text{else.} \end{cases} \quad (9)$$

For various types of nonlinear equations, it is easy and straightforward to use the theorems proved in Chap. 4 of Liao's book (Liao 2011a) to calculate the term $R_k(\mathbf{r}, t)$ of the high-order deformation Equation (7).

When we get the m th-order deformation equations and the initial approximation $u_0(\mathbf{r}, t)$, the auxiliary linear operator $\mathcal{L}$ and the auxiliary function $H(\mathbf{r}, t)$ are properly chosen, the $u_m(\mathbf{r}, t)$ can be got order by order. The solution of the high-order

deformation Equation (7) can be expressed in the form

$$\begin{aligned} u_m(\mathbf{r}, t) = -\chi_m u_{m-1}(\mathbf{r}, t) \\ + \mathcal{L}^{-1}[c_0 H(\mathbf{r}, t) R_{m-1}(\mathbf{r}, t)]. \end{aligned} \quad (10)$$

where $\mathcal{L}^{-1}$ is the inverse operator of $\mathcal{L}$. At this time, we get the solution $u(\mathbf{r}, t)$ containing the "convergence-control parameters" c_0 . By choosing the appropriate c_0 , we can get a fast convergence solution.

Base Function and Some Fundamental Rules

It is well known that a real function $u(\mathbf{r}, t)$ can be approximated by many different base functions and thus can be more efficiently approximated by a relatively better set of base functions. For example, if $u(t) = 1/(1+t)$ is expressed in power series, we have

$$u(t) \sim 1 - t + t^2 - t^3 + \dots \quad (11)$$

which only converges in the region of $|t| < 1$. But, if we choose

$$1, \frac{1}{1+t}, \frac{1}{(1+t)^2}, \frac{1}{(1+t)^3}, \dots \quad (12)$$

as the base function, the exact solution can be got by only one item. The type of base function is therefore rather important for the efficiency of approximating a nonlinear problem. The key of efficiently approximating a given nonlinear problem is to choose a relatively better set of base function. Different from the perturbation and non-perturbation methods, the first step to apply HAM is choosing a proper base function. In many cases, by mean of analyzing its physical background and/or its initial/boundary conditions and/or its type of nonlinearity, we might know what kinds of base functions are proper to represent the solution, even without solving a given nonlinear problem. In this entry, let

$$\{e_k(\mathbf{r}, t) | k = 0, 1, 2, \dots\} \quad (13)$$

denote such a set of base function for the illustrative nonlinear problem (1). We can represent the solution in a series

$$u(\mathbf{r}, t) = \sum_{n=0}^{+\infty} c_n e_k(\mathbf{r}, t), \quad (14)$$

where c_n is a coefficient. As mentioned above, a real function $u(\mathbf{r}, t)$ might be expressed by many different base functions. Thus, there might exist some different kinds of solution expressions and all of them might give accurate approximations for a given nonlinear problem. In this case, we might gain the best one by choosing the best set of base function. The solution Expression (14) is the starting point of the HAM and is of great significance in the framework of the HAM.

When we choose the set of base function of the nonlinear problem, the solution expression is determined. Then, based on the solution expression, we can choose the initial approximation $u_0(\mathbf{r}, t)$, the auxiliary linear operator $\mathcal{L}$, and the auxiliary function $H(\mathbf{r}, t)$ by some principles. In Chap. 2 of Liao's book (Liao 2003), Liao proposed the following three principles to guide the selection of $u_0(\mathbf{r}, t)$, $\mathcal{L}$, and $H(\mathbf{r}, t)$:

1. Rule of solution expression: The auxiliary function $H(\mathbf{r}, t)$, the initial approximation $u_0(\mathbf{r}, t)$, and the auxiliary linear operator $\mathcal{L}$ must be chosen in such a way that all solutions of the corresponding high-order deformation equations exist and can be expressed by this set of base functions.
2. Rule of coefficient ergodicity: All coefficients in the solution expression, such as c_n in (14), can be modified to ensure the completeness of the set of base functions.
3. Rule of solution existence: The high-order deformation equations should be closed and have solutions.

The so-called *rule of solution expression*, *rule of coefficient ergodicity*, and *rule of solution existence* play important roles and greatly simplify the application of the HAM.

The "Convergence-Control Parameter" c_0

Independent of small/large physical parameters, the HAM provides us great freedom. Using this kind of freedom, we introduce a nonzero auxiliary parameter c_0 , namely the "convergence-control parameter," into the so-called zeroth-order deformation Equation (2). When a set of base function is determined and the initial approximation $u_0(\mathbf{r}, t)$, the auxiliary linear operator $\mathcal{L}$ and the auxiliary function $H(\mathbf{r}, t)$ are all be chosen properly. Note that, the high-order deformation Equation (7) contains the convergence-control parameter c_0 . Therefore, we can get the HAM series which also contain the "convergence-control parameter" c_0 . More importantly, we have great freedom to choose the value of c_0 so that we can find some proper values of c_0 to guarantee the convergence of the HAM series. Thus, the "convergence-control parameter" c_0 provides us a convenient way to guarantee the convergence of HAM series. Note that the introduction of the so-called "convergence-control parameter" c_0 in the zeroth-order deformation Equation (2) is a milestone for the HAM.

From physical viewpoint, the "convergence-control parameter" c_0 has no physical meanings so that convergent series of solution given by the HAM must be independent of c_0 . This is indeed true: there exists such a region $\mathbf{R}_c$ that, for arbitrary $c_0 \in \mathbf{R}_c$, the HAM series converges to the true solution of the original Equation (1), as illustrated by Liao (2003, 2011a). However, if $c_0 \notin \mathbf{R}_c$, the solution series diverges! So, from a mathematical viewpoint, the "convergence-control parameter" is a key point of the HAM, which provides us a convenient way to guarantee the convergence of the solution series (6). In fact, it is the "convergence-control parameter" c_0 that differs the HAM from all other analytic methods.

At the m th-order of approximation, the optimal value of the convergence-control parameter c_0 can be determined by the minimum of residual square of the original governing equation, i.e.,

$$\frac{d\epsilon_m}{dc_0} = 0, \quad (15)$$

where

$$\varepsilon_m = \int_{\Omega} \left\{ \mathcal{N} \left[\sum_{n=0}^{+\infty} u_n(\mathbf{r}, t) q^n \right] - f(\mathbf{r}, t) \right\}^2 d\Omega. \quad (16)$$

Besides, it has been proved by Liao (2003) that a homotopy series solution (6) must be one of solutions of considered equation, as long as it is convergent. In other words, for an arbitrary convergence-control parameter $c_0 \in \mathbf{R}_c$, where

$$\mathbf{R}_c = \left\{ c_0 : \lim_{m \rightarrow +\infty} \varepsilon_m(c_0) \rightarrow 0 \right\}, \quad (17)$$

is an interval, the solution series (6) is convergent to the true solution of the original Equation (13). For details, please refer to Liao and Chap. 3 of his book (Liao 2011a). Up to now, as the convergence-control parameter c_0 is determined, the convergence solution $u(\mathbf{r}, t)$ can be got successfully based on the HAM.

Applications of HAM

HAM is an analytic technique for highly nonlinear problems and has been successfully applied for nonlinear problems in various areas which governed by various types of ordinary differential equations (ODEs) and partial differential equations (PDEs), such as boundary-layer flows (Liao 2005; Liao and Magyari 2006), finance (Cheng et al. 2010; Zhong and Liao 2017a; Zhu 2006), water waves (Liao 2011b; Liao et al. 2016; Liu and Liao 2014; Liu et al. 2018; Xu et al. 2012; Yang et al. 2018; Zhong and Liao 2018b), and so on (Zhong and Liao 2017b, 2018a). Here we mainly introduce the applications of HAM on water waves which are governed by complicated nonlinear PDEs.

Liao (2011b) considered the nonlinear interactions between pairs of intersecting wave train in deep water which exactly satisfied the resonance criterion and found steady-state resonant gravity waves by means of the HAM for the first time, to the best of our knowledge. Then it was found that the steady-state resonant gravity waves exist not only in infinite water depth but also in finite water

depth by Xu et al. (2012). Note that Liao (2011b) and Xu et al. (2012) only consider a special quartet. Liu and Liao (2014) further extended the existing results for steady-state resonance from a special quartet to more general and coupled quartets, together with consideration of higher-order resonant interactions. The significant role of the near resonance was revealed. It was found that all near-resonant components as a whole contain more and more wave energy, as the wave patterns tend from two-dimensional to one-dimensional, or as the amplitudes of the steady-state resonant wave system increase, as pointed out by Liu and Liao (2014). What is exciting is that the existence of steady-state resonance waves were confirmed experimentally by Liu et al. (2015). These steady-state resonant waves are first calculated theoretically under the exact resonance criterion with sufficiently high nonlinearity, and then are generated in the basin at the State Key Laboratory of Ocean Engineering (SKLOE) in Shanghai by means of the main wave components that contain at least 95% of the wave energy. The comparison of experimental results and theoretical results are shown in Figs. 1 and 2. In addition, about the steady-state gravity waves, Liao et al. (2016) successfully applied the HAM to obtain the steady-state nearly resonant gravity waves in deep water, and Liu et al. (2018) found finite amplitude steady-state waves with multiple near-resonant interactions. Recently, the steady-state acoustic-gravity waves were also obtained by Yang et al. (2018). It was found that the dynamic pressure on the sea bottom caused by the resonant hydroacoustic wave component is much larger than that in the case of non-resonance, which might even trigger microseisms of the ocean floor. This will greatly deepen and enrich our understandings about resonant waves.

Moreover, on the limiting Stokes wave of extreme height in arbitrary water depth, Zhong and Liao (2018b) gained convergent results of the limiting Stokes waves with this kind of sharp crest in arbitrary water depth, even including solitary waves of extreme form in extremely shallow water, based on HAM and found that, in the frame of the HAM, the Stokes wave is a unified theory for all kinds of progressive waves, even including

Homotopy Analysis Method, Fig. 1 Perspective plot of the free-surface in case S1 in (Liu et al. 2015). Crests in the middle region are marked as yellow lines. (a) Experimental result; (b) theoretical result

Homotopy Analysis Method, Fig. 2 Perspective plot of the free surface for case S3 (Liu et al. 2015). Crests in the middle region are marked as yellow lines. (a) Experimental result; (b) theoretical result

the limiting (extreme) solitary waves with a sharp crest of 120° angle in extremely shallow water, as shown in Fig. 3.

All of these successful applications show the originality, validity, and generality of the HAM for nonlinear problems in science and engineering.

Conclusion

As mentioned above, the HAM has the following advantages:

- It is independent of any small/large physical parameters.
- It provides us great freedom and large flexibility to choose equation type and solution

expression of linear high-order approximation equations.

- It provides us a convenient way to guarantee the convergence of approximation series.

In this way, nearly all restrictions and limitations of the traditional perturbation method and non-perturbation methods (such as Lyapunov's artificial small parameter method, the δ -expansion method, the Adomian's decomposition method, and so on) can be overcome by means of the HAM. Besides, it has been generally proved that the Lyapunov's artificial small parameter method, the Adomian's decomposition method and the δ -expansion method are only special cases of the HAM for some specially chosen auxiliary linear operator $\mathcal{L}$ and convergence-control parameter c_0 . Thus, the HAM is more general in theory.

Homotopy Analysis Method,

Fig. 3 Comparison of H/d versus λ/d . Williams (1981): circle; the first-order HAM-based iteration approach: solid line; demarcation line between Stokes and cnoidal theories, the Ursell number (Hedges 1995): dash-dot line; for solitary wave (Hunter and Vanden-Broeck 1983): dashed line

The HAM provides a useful analytic tool to investigate highly nonlinear problems with multiple solutions and singularity in science, finance, and engineering. Based on HAM, we have truly got new solutions that were even missed by numerical methods of some nonlinear problems. It shows us the validity and great potential of HAM and encourages us to apply the HAM to attack some challenging nonlinear problems.

Definition

Human factors is the application of psychological and physiological principles to the engineering and design of products, processes, and systems. The goals of human factors are to reduce human error, increase productivity, and enhance safety and comfort with a specific focus on the interaction between human and things of interest.

In the nineteenth century, Frederick Taylor pioneered the “scientific management” method, which proposed a way to find the optimum method of carrying out a given task. Frank and Lillian expanded Taylor's methods in the early 1900s to develop the “time and motion study.” They aimed to improve efficiency by eliminating unnecessary steps and actions.

Human factors is a broad-based discipline and has always played a role in the design and operation of ship. However, advancing and applying human factors has been an uneven and thorny process throughout history. Knowledge to be permanently embedded in practice has been commonly discarded and must be relearned, often at great human cost.

The dawn of the Information Age has resulted in the related field of human–computer interaction. Likewise, the growing demand for and competition among marine products have resulted in more companies and industries including human factors in their product design.

Scientific Fundamentals

Human factors is a combination of numerous disciplines, such as psychology, sociology, engineering, biomechanics, industrial design, physiology, anthropometry, interaction design, visual design, user experience, and user interface design (Mccormick and Sanders 2002). In essence, it is the study of designing equipment, devices, and processes that fit the human body and its cognitive abilities.

Human factors is employed to fulfill the goals of occupational health and safety and productivity. It is relevant in the design of such things as safe furniture and easy-to-use interfaces to machines and equipment.

Human factors is concerned with the “fit” between the user, equipment, and environment. It accounts for the user's capabilities and limitations in seeking to ensure those tasks, functions, information, and the environment that suit the user.

There are many specializations within these broad categories. Specializations in the field of physical ergonomics may include visual ergonomics. Specializations within the field of cognitive ergonomics may include usability, human–computer interaction, and user experience engineering.

Physical ergonomics is the science of designing user interaction with equipment and workplaces to fit the user. It is concerned with human anatomy and some of the anthropometric, physiological, and biomechanical characteristics as they relate to physical activity.

Cognitive ergonomics is concerned with mental processes, such as perception, memory, reasoning, and motor response, as they affect interactions among humans and other elements of a system.

Organizational ergonomics is concerned with the optimization of sociotechnical systems, including their organizational structures, policies, and processes (Fig. 1).

Key Applications

The primary consideration in the safe design and operation of ship is the “human factors,” the detrimental impact on safety of the ship, its crew, cargo, and the maritime environment.

The ship architect, marine engineer, other design specialists, analysts, and operators have influence over a number of important design elements that can enhance human factors in a ship. Examples of these elements include the following: hull form (ship motions), structure, machinery (vibration, noise, condition), general arrangements (accommodation, life at the sea), etc.

Hull Form

Ship includes all ships and craft which move on, under or across the surface of the water. Certain hull types are by their nature more stable than others or more prone to produce motions that

enhance operator performance and embarked personnel comfort.

At the design progresses, there are six disciplines that should be considered: avoid frequencies between 0.125 and 0.250 Hz; avoid high impact (shock); appropriate length, beam (hull and overall), and centers of gravity and rotation; sufficient wet deck clearance; appropriate for different operating configurations; and appropriate for expected sea conditions (Figs. 2 and 3).

Human Factors in Ship Design, Fig. 1 Physical ergonomics: the science of designing user interaction with equipment and workplaces to fit the user (https://en.wikipedia.org/wiki/Human_factors_and_ergonomics)

Human Factors in Ship Design, Fig. 2 Ship's six freedom motion: 1. heave, 2. sway, 3. surge, 4. yaw, 5. pitch, 6. roll (<https://en.wikipedia.org/wiki/Ship>)

Structure

This section provides three guidance materials to help ensure continued consideration of human factors. Examples of these rules include the following: avoid frequencies between 4 and 0 Hz, maintain accelerations below 0.315 m/s^2 , survive worst-case loading.

Machinery

In this part of work, approaches for enhancing human factors are listed below: decreased vibration and airborne noise isolation, condition monitoring, and hearing protection.

Airborne noise often begins as structural vibration caused by diesel engines, and is transmitted directly or through a combination of structure and air into surrounding compartments.

The vibration may be low frequency, such as when a vehicle meets waves, or high frequency, such as that driven by heavy rotating machinery (Fig. 4).

General Arrangement

Ship is limited in their capacity to carry weight or enclose volume and to generate propulsion and service power. Limitations and potential design responses are developed and compared during the early phases of a ship design. These "trade studies" or "analyses of alternatives" consider numerous technical requirements and recently have begun to consider human factors requirements as well.

Accommodations do not include machinery spaces or operational spaces. In designing accommodation spaces, consideration should be given to

Human Factors in Ship Design, Fig. 3 Body plan of a ship showing the hull form (https://en.wikipedia.org/wiki/Ship)

Human Factors in Ship Design, Fig. 4 A ship's engine room: the main source of ship vibration and noise (https://en.wikipedia.org/wiki/Ship)

stateroom deck area, and the size, shape, and fittings associated with doors, stairs, furniture, and corridors. Stairs tend to be steeper, and there is more noise and vibration on ship. Other considerations with regard to accommodations include

ship motion, lighting, temperature, ventilation, and colors (Fig. 5).

Access refers to the means provided for people to move about the ship in vertical and horizontal directions. The designers make trade as

Human Factors in Ship Design, Fig. 5 Accommodations onboard (<https://cn.bing.com/images>)

Human Factors in Ship Design, Fig. 6 Evacuation onboard (<https://cn.bing.com/images>)

whether to maintain watertight integrity with a high skilled, dogged steel door tithe weather deck or easy passage with a nontight swinging door. Safety against the sea, weather, hostile combat action, and the ability to move about the ship unhindered are all design considerations within the realm of access.

Safety at sea is always a concern; designers can enhance safety by numerous means including reinforced structural closures, additional handholds in showers and in dimly lit public areas, decreasing or eliminating deck height changes, marking leading edges of stair steps, ensuring life jackets are easily available, and including stateroom balconies in fire boundaries (Figs. 6 and 7).

Life at Sea is defined by routine. Training exercises encompass fire, flooding, and simulated combat. Some training is grueling and as close to

the mental and physical rigors of combat as the instructors can simulate.

Symptomatic areas of concern are those events or conditions that affect a person's comfort or performance and may be describable only by the person involved in symptomatic areas of concern. There are five symptomatic areas of concern relevant to the design and operation of marine vehicles: motion sickness, spite syndrome, fatigue, sleep loss, and human error.

Human stressors are physically measurable events or stimuli that affect the comfort or performance of a person.

Human–Machine Interface

The human–machine interface is where communication and physical interaction occur between the individual operator or embarked person and a particular component of the ship. Paying attention

Human Factors in Ship Design, Fig. 7 Lifeboat onboard (<http://image.baidu.com/>)

Human Factors in Ship Design, Fig. 8 The human-machine interface (<http://image.baidu.com/>)

to the human-machine interface during the design process will enhance personnel comfort and operational effectiveness, information availability, safety, appropriate automation, and commonality of instruments and control commonality, and decrease fatigue, human error, duplication of effort among crew members, and training requirements (Fig. 8).

Future Trends

Human factors is recognized as an important element of design process, though presently this element receives much more lip service than funded tasking in both the naval and commercial worlds. That said, navies and commercial owners are beginning to increase their funding to human factors as a way to improve operator performance and enhance the comfort of embarked personnel.

Several trends pull human factors to the forefront of marine vehicle design and operation:

Crew sizes: The first of these trends, observed by all in the marine industry, is the move toward reduced crew sizes. This trend is driven by the high cost of qualified personnel and the increasing capability and availability of automation, which can replace crew personnel with remote sensors and controls. The trend is further advanced through enhanced maintenance practices, which focus on less maintenance at sea by the crew, and the change from periodic maintenance at set time intervals to condition-based maintenance and requirement-based maintenance. Interlaced with this trend are issues involving safety and habitability.

Computer capabilities: The second trend is increased computer capabilities, in the field of

design in general, and also in the specialized fields of computer-aided modeling and simulation. Simulation enables the prediction of technical parameters such as speed, power, and ship motions. Simulation also has advanced in the field of human performance, with models addressing task allocation among vehicle operators, as well as personnel performance under stressors such as sleep loss, noise, and temperature extremes. Finally, the capability to link software programs has increased exponentially in recent years, enabling designers to communicate between ship behavior programs and human performance programs.

Safety considerations: Maritime operating organizations have come to realize that the vast majority of incidents and accidents are caused by human errors, either by designers or operators. These organizations are concerned with injuries and deaths, and are beginning to apply human factors techniques to increase safety.

Regulatory changes: Likewise, regulatory agencies have studied the trends, have recognized the role of human factors, and are revising regulations to help prevent incidents and accidents that can cause human and environmental losses.

Human factors research and development are expensive in the larger sense, but acceptable on the incremental level, project by project. Thus, human factors advancement will probably continue to be evolutionary and not revolutionary. The following trends appear reasonable:

- (a) Reduced crew size coupled with increased automation – This overarching trend, motivated by life cycle cost reductions, will likely continue, with more and more human functions replaced by automation.
- (b) Performance predictions – Future research may be aimed at developing techniques to better understand the relationships among motion, fatigue, sleep loss, and spaced syndrome and be better able to predict the resulting drops in operator performance and personnel comfort (Bri2003).
- (c) Enhanced interoperability – Interoperability issues will be addressed, enabling an

increased flow of information among commercial and naval operators (Clark and Moon 2001).

- (d) Operator performance linked to vehicle sea keeping – This integration will enable designers to predict the effect of design changes on operator performance, including cognitive performance, physical performance, and predictions of MSI and MII (Colwell 2006).
- (e) Augmented cognition – The present human–computer interface will evolve to a human–computer symbiosis system that includes artificial intelligence. In this system, extensive information will be available to the human in real time. Distributed, autonomous systems, intelligent agent architectures, and wireless communication will help make the operator aware of critical information upon which to base decisions (Masakowski 2008).
- (f) Predictive models for effective seat design – Improved spinal injury models will become available to better predict the health effects of repeated impact loading in high-speed craft in rough seas (Bass et al. 2005a, b; Peterson et al. 2004).
- (g) Enhancement of bridge controls and arrangement – Human factors considerations with regard to bridge controls and arrangement will continue to advance, with software increasing in sophistication and flexibility, allowing monitors and controls to be more readily adapted on the fly for individual users and specific missions or situations (Bowdler et al. 2005, Widdel and Motz 2000).
- (h) Ship evacuation – Particularly from ships carrying many personnel (e.g., cruise ships, aircraft carriers) – is an area with potential for safety improvement. Areas of investigation could include the effect of lifejackets on personnel mobility (Igloliorte et al. 2006). The results can be used to further validate and enhance programs such as maritime EXODUS (Earl 2002).
- (i) Robotic fire fighters – One idea that could place the human out of harm's way is to employ firefighting robots inside the danger

zone, backed up by human operators a safe distance away (Sheridan 1992).

Definition

Energy is an important source for economic and social development in the world. It is even more indispensable in today's fast-growing transportation industry. With the development of transportation in the past few decades, carbon dioxide emissions have increased significantly. The shortage of energy and the emission of waste heat from waste gas have intensified, making the importance and necessity of energy saving and emission reduction of ships particularly remarkable (ABS 2015). According to the main factors affecting ship energy consumption and emission reduction, some methods for energy saving and emission reduction of ships can be divided into ship design, construction, operation, and management (Bailou 2013). In addition to the technical development of those energy efficiency measures, how much benefits of installing an energy efficiency measure can be obtained by a ship strongly depends on the crew members who directly operate these technologies. For maritime transport, more than 60% of accidents are attributed to human-related operations (UNCTAD 2019). Therefore, a good understanding and utilization of the role of human factors in shipping energy efficiency will greatly increase

the working efficiency of those energy efficiency measures to be implemented by ships.

Technical Improvement of Energy Efficiency

From traditional naval architecture perspective, to increase a ship’s energy efficiency is to reduce a ship’s sailing resistance at sea and increase the propulsive efficiency from marine engine and propellers, e.g., Harvald (1983), Lewis (1988), etc. A straightforward approach to increase a ship’s energy efficiency is through better ship design and construction (Bailou 2013). In the design process, a workflow to optimize a ship’s hull geometry is presented in Fig. 1. Linear optimization refers to the design of the ship’s hull line type (U- or V-type), water line inflow, and outflow angles (Holtrop and Mennen 1982). The current design optimization process can use model tests and CFD (computational fluid dynamics) methods to adjust a ship’s hull geometry, repeatedly (Seo et al. 2013; ITTC 2014). Then the final hull geometry of the design ship will be optimized with relative low resistance in a ship’s actual sailing environment. Furthermore, another way to increase a ship’s energy efficiency is to improve the propulsion efficiency

of the ship mainly by improving the tail flow field and the power consumption of the main engine (DNV GL 2014).

The improvement of the tail semi-flow field refers to the installation of the propeller fairing on the ship hull. Moreover, currently existing ship can choose to install high-efficiency and energy-saving power equipment, including main and auxiliary engines, boilers, and drive shaft systems. At present, the diesel engine as the main propulsion device tends to develop in the direction of low speed, long stroke, high pressure, high compression, and electronic injection and can burn inferior fuel oil. Since the diesel engine is working under partial load, its economy is poor, and the fuel consumption rate is increased. When some ships are working under partial load for a long time, the main shaft can be used with the generator, which not only enables the main machine to work in an efficient operation area and improves efficiency but also reduces the number of diesel generator sets. In addition, some electric heating can be installed to a ship’s fuel pipeline to improve the fuel temperature, reduce the viscosity and surface tension of the fuel, improve the atomization performance, and thus improve the fuel combustion and nitrogen oxide emissions. Other technologies related to marine engine systems to reduce air emissions include installation of a

Human Factors in the Role of Energy Efficiency, Fig. 1 Design of linear for low resistance (Lewis 1988)

homogenizer for the fuel system; adding fuel additives to fuel which can improve fuel quality, improve combustion performance, reduce harmful emissions, improve fuel utilization, and reduce harmful emissions and energy; and development of new alternative fuels such as marine fuels, waste heat recovery systems, etc.

Ship Energy Efficient Management Plan

From human factor perspective, the management strategy of a ship's operation is one of the key steps to increase a ship's energy efficiency (Bännstrand et al. 2016). In the management process, captains, together with the traffic management team, are required to rationally design the route plan and strive for the economy on the premise of ensuring safety, by taking full consideration of the meteorological factors of the route and the voyage's waves, surges, and wind flow factors to avoid disastrous wind/wave conditions and optimally utilizing ocean currents in sailing. According to pirate information, avoid high-risk waters where pirates are infested. For example, if a super-large oil tanker is mainly engaged in the transportation of crude oil from the Middle East or Africa to the Far East, it should not only understand the seasonal weather information of the Indian Ocean but also have a good understanding of the information of the pirate's infested waters. The route design should be particularly serious and meticulous. Although it is possible to protect the safety of ships by avoiding pirate-infested waters, it is also necessary to consider designing the best economic routes. Large oil tankers have high freeboards and are equipped with anti-pirate wires and anti-pirate devices from the front to the rear. When there are more than 5 kn winds in the Indian Ocean and more than 1.5 m, the possibility of pirates will be greatly reduced (OECD 2015). When sailing in the waters of pirates, the navigational watch should be strengthened, and the patrol personnel should be arranged to make emergency plans and countermeasures for possible situations.

Implement an Energy Efficiency Management Plan

Develop and implement a ship energy efficiency management plan for energy efficiency targets and indicators on all ships and adopt the best operational plan according to the ship's own characteristics, navigation area, trade, and other related requirements. It has achieved good results in improving the energy conservation awareness of ship and shore management personnel and reducing fuel consumption.

Electromechanical equipment is the most direct consumer of ship oil materials. Grasp the maintenance of electromechanical equipment, ensure that electromechanical equipment is in good working condition, and fully tap energy saving and emission reduction. Maintain the main engine and auxiliary engine (diesel engine) as required; keep the intake and exhaust system, fuel system, lubrication system, and cooling system in good condition; and regularly clean and repair the exhaust turbocharger, injector, and combustion chamber components. Keep the working conditions of the main and auxiliary machines in good condition and the thermal efficiency in best condition.

Maintain boilers and exhaust gas boilers according to requirements, adjust the correct proportion of wind oil, and regularly clean the oil guns to ensure good combustion. Regularly blown and clean surface of the furnace and collector tubes can ensure good heat transfer effect, and regularly reduce water quality. The heating of the cargo oil tank and the fuel oil tank should also be optimally arranged to reduce the fuel consumption of the oil-fired boiler. Ship crew and onshore management team should use the characteristics of cargo oil and berthing unloading plan, to better arrange cargo heating and unloading operations and minimize the time of cargo oil heating and unloading time to save fuel consumption.

A ship's draft and trim should be optimized by ballast water to ensure the efficiency of the propeller and reduce resistance. An optimal ballast tank sediment management plans, flush regularly, and control sediment accumulation can help to reduce unnecessary energy consumption. When

carrying out ballast water operation, the gravity discharge system should be considered to reduce the fuel consumption of the ballast pump. The ballast process for each voyage requires a ballast plan based on the quality of the ballast water at the port of discharge. In addition, ship crews should regularly check the condition of the hull and propeller, evaluate the condition of the hull and the propeller, and find out that the underwater hull is cleaned in time when the hull has big biofouling; check whether the propeller has foreign matter entangled, and if it should be removed as soon as possible, eliminate the navigation of the ship.

Increase Awareness of Energy and Emission Reduction

Ship management team should help to increase the awareness of energy consumption and emission reduction work for ship crews (Bailou 2013; DNV GL 2014). From legislation perspectives, maritime authorities and environmental policy makers should continuously implement regulations and provide financial subsidies to encourage the early elimination of old fashion energy-intensive systems. Further enhancement of environmental regulations on shipping emission control zones can promote the utilization of energy efficiency technologies and new energy sources and increase awareness of pollutions from shipping from whole transport market perspectives. At present, the major incentive of energy saving and emission reduction of current shipping companies is to save costs, but in terms of long-term interests, most enterprises are not very clear about the significance and importance of energy saving and emission reduction. The most important thing for enterprises to do energy consumption and emission reduction is to make enterprises fully aware of the importance of energy conservation and emission reduction. That is to fully raise awareness of energy saving and emission reduction within the company. It is important to make all company members recognize the importance of energy saving and emission reduction. Shipping companies can introduce more indicators, guidelines, policies, etc., to

highlight the significance of energy saving and emission reduction. Through various channels, such as setting up energy-saving emission reduction bulletins and slogans within shipping companies and grassroots, actively carry out publicity and education activities on energy-saving and emission reduction work within the shipping industry, turning energy saving and emission reduction into another work focus besides pursuing economic benefits. Another efficient way is to create good forum for ship operators to communicate and demonstrate the actual benefits of various energy efficiency measures to reduce fuel consumption and air emissions. It can also provide end-users with good communication and training platforms regarding how to implement these measures.

Optimal Ship Operation

Because of master mariners' lack of capability to continuously adjust a ship's operation profiles (speed/course), ships are not navigated in an energy efficient manner, leading to large waste of fuel cost and emissions (Wang et al. 2017). As the ship size increases, large ships need long time for turning and stalling. Therefore, for an efficient navigation, small steering angles should be used as early as possible to allow the ship speed to drop as much as possible. When sailing in a narrow waterway, the steering is mainly controlled by small adjustment of rudders. When sailing at sea, whenever the steering point is reached, captains usually change to the next heading immediately, leading to significant speed drop after the steering is completed. Therefore, to use the stepwise steering to slowly adjust the ship sailing to the next heading before the arrival of the turning point can also save fuel cost during the sailing at sea. To optimize the operation of cargo loading and unloading can be quite beneficial to reduce the fuel burning and air emissions at the port. The first officer shall be responsible for organizing and formulating a complete plan for loading and unloading cargo according to the relevant loading requirements of the voyage order, ship equipment, personnel, and port status. The deck department

and the engine department should fully communicate with each other to clarify the time for unloading and starting the pump. This management could help to avoid the idling of the cargo pump and make the auxiliary boiler run for a long time and waste fuel. Take a 76,000 DWT tanker, for example. In the case of the same total power load, each additional auxiliary machine will run an additional 1 t of fuel per day. If you stop the unnecessary pumps, oil pumps, and fans during the suspension to save fuel, you can save about 1 t of fuel per day.

Role of Human Factors in Energy Efficiency Measures

For all energy-saving and emission reduction methods, human factors play an indispensable role (IMO 2003). For example, Fig. 2 presents some brief introduction of a ship’s voyage planning process to identify an economic speed for

the navigation. The establishment of the ship economic speed and the route distribution model must include intensively human involvement. Therefore, experts can only rely on their rich knowledge reserves and navigation experience and case analysis of past actual route design to plan and judge the route. It is more conducive to ship navigation and energy saving. In the ship operation process, technical persons are required to carry out data statistics on ship operation information, economic benefits, and the company’s current situation and report it to the management. The management team combines the company’s development policy to discuss, analyze, and try to make a low-cost and high-efficiency plan to benefit the shipping company. The implementation of those planned energy saving, and emission reduction measures requires transparent communications among employees at all different levels. The implementation of energy saving and emission reduction.

Human Factors in the Role of Energy Efficiency, Fig. 2 A brief introduction of a ship’s voyage planning process to determine an economic speed (IMO 2000)

In order to ensure the timeliness of the port information during the voyage, all parties should communicate in a timely manner. Captains are responsible for the communication with the shipping department, optimizing the ship speed according to the loading and unloading plan and rationally formulating the ship replenishment plan, time schedule of parking, loading, unloading, etc. Because of the variability of the actual situations, some plans need to be revised at any time after the multiparty communication gets instant information. The current system is not perfect enough to cover all aspects in the ship operation process. Some modifications are needed even during a ship's sailing stages according to the instant information. In general, it is still necessary to rely on the management of the ship to make plans based on their own professional knowledge and navigation experience. The rationality of the plan largely determines the degree of energy savings.

In the process of managing the inspection and maintenance of a ship's main equipment to achieve energy-saving effect, human participation is of particular importance, such as the maintenance of main engines and the auxiliary engines (diesel engine), the boiler and exhaust gas boilers, regular flushing of ballast water in the optimization of ship ballast to control sediment accumulation, and regular inspection and cleaning of hulls and propellers. During the management process, the crew must be strictly implemented according to the plan, while the responsibility should be assigned to specific crew members rather than any kind of computer systems (Tillig et al. 2017).

In the method of strengthening the awareness of energy saving and emission reduction in shipping, it is the formulation of government policies or the promotion and training of enterprises and various stakeholders of the entire shipping industry. Only by raising the awareness of people can we grow from small details to large implementation of more energy efficiency measures onboard ships. In the worst case, seafarers may not believe (or do not aware the usage of) these energy efficiency measures that are bought by shipping companies to reduce fuel cost and air emissions. The lack of communication between ship operator

management and seafarers can lead to large waste of energy saving potential and investment.

On the other side, if it is promoted properly, the human factors can play a big positive impact to increase a ship's energy saving and reduce emission during her service period. For example, in a ship's design and operation process, simply relying on technical systems cannot fully consider all aspects of ship energy influence factors. Large deviation of a ship's performance characteristics during the design and planning stages can be expected from the ship's actual sailing situations. Manual participation can often be considered more comprehensively, and the proposed scheme can be more practical. Furthermore, information exchange between the onboard crew member and onshore stakeholders such as ship traffic management team, ports, shippers, weather providers, etc. should be more transparent and faster, which can help to adjust a ship's operation plan immediately to reflect the actual sailing status. For example, when the ship is sailing, if needed she can in real time communicate with the port, agent, terminal, cargo owner, and company dispatch and understand the congestion of the port, the time of entry and exit, the berth handling capacity and the plan, etc. All those steps must involve humans from different stakeholders, in order to update original sailing plan according to the real-time situation and improve the navigation and operational efficiency of the ship. In the event of an emergency or an emergency, the worker can respond quickly and in a timely manner.

Furthermore, the involvement of human factors in a ship's navigation process could be enhanced to allow more efficient navigation manner. For example, in today's ocean crossing ships, it is quite common to order weather forecast to guide a ship's navigation. Based on the forecast sea environment conditions, a correct steering mode can be determined to minimize the ship's fuel consumption. In this case, the single auxiliary machine is used as much as possible to reduce the unnecessary power load; the ship should pass the pressure before starting the ship; the water loading regulation of the ship's draft and reasonable trim, to ensure the efficiency of the propeller and

other details of the operation, can only be fully automated, etc.

It can better appeal to the awareness of energy saving and emission reduction in the entire shipping industry. By setting an example for implementing energy-saving and emission-reducing programs and paying attention to energy conservation and emission reduction in detail, it is better to transmit this spirit to others. Starting from the subtleties, the implementation of energy efficiency and emission reduction technologies can be more effectively promoted.

However, if human factors are not properly considered in a ship's operation process, it will lead to negative impact of generating more emissions and cost more fuels during sailing. In the ship design and route planning, even experts may be negligent, because the calculation of some details is not enough for the consideration is not comprehensive. Neglecting some important factors may lead to large deviations, making the result unsatisfactory. When the technicians conduct statistics on ship operation information, economic benefits, and the company's capital status, due to the huge amount of information and complexity, it is more prone to errors, which may lead to the company's management finally getting the wrong information for ship operations. Making wrong decisions leads to a sudden drop in economic benefits and hinders the development of energy efficiency and emission reduction.

Due to the inspection and maintenance schedule of the ship equipment, large amount of human participation is required for the reasonable operation of the ship during navigation. The whole process is prone to errors in management and brings a certain degree of trouble to management planning. Therefore, it is necessary to establish a cumbersome management mechanism system with clear responsibilities to reconcile the artificial relationship between some contradictions. The planning process requires a lot of time and resource investment, while the final inspection and benefit analysis may be also associated with high cost but definitely necessary from end-users to realize the actual benefits. If the process chain is not handled properly, the shipping industry may

become hesitated to invest and implement energy efficiency measures.

Definition

A **human occupied vehicle** (HOV), also known as **manned submersible** (MS) is one type of **submersibles** which can carry scientists, engineers, and various electronic devices and special equipment to arrive at various deep-sea complex environments quickly and accurately, and conduct efficient exploration, scientific investigation, and other deep sea operations. It is an important technical means to understand the ocean phenomena and to exploit the ocean resources. A typical manned submersible consists of four major components: a pressure hull, propellers (thrusters), buoyant materials, and observational and sampling instruments. Currently there are four types of different HOVs: manned submersible (MS), deep submergence rescue vehicle (DSRV), atmospheric diving suit (ADS), and rescue bell.

Scientific Fundamentals

Historical Development

Human curiosity for the natural world and human exploitation of ocean resources are the first two factors for the progress of deep ocean exploration while man's quest to achieve mobility beneath the surface of the sea for military purposes is the third but the most important factor to speed up the development of deep sea manned submersibles (Nash 1995).

The first modern deep diving by humans, to a depth of 923 m, was achieved in 1934 by William Beebe (1877–1962), an American zoologist, and Otis Burton (1899–1992) using the bathysphere, which means 'deep sphere.' The bathysphere was a small spherical shell made of cast iron, 135 cm of inside diameter designed for two observers. The bathysphere had an entrance hatch and a small glass view port. As the sphere was lowered by a cable and lacked thrusters, it was impossible to maneuver (Hotta et al. 2001). It was the beginning of the modern era of humans entering the deep abyss in a pressure resistant hull. Their discoveries were summarized in two books "Half Mile Down" (Beebe 1935) and "The World Beneath the Sea" (Barton 1953).

Manned observations using the Bathysphere in the deep sea rewarded the researchers with views of live marine life. However, it cannot dive to a very deep depth due to the self-weight of the cable. Auguste Piccard (1884–1962) was the first to design a submersible without the use of steel cables. It occurred after World War II, in 1947. The bathyscaph FNRS II was invented by Auguste Piccard, who had been studying cosmic rays using a manned balloon in Switzerland. The principle of the bathyscaph was the same as that of a balloon. Instead of hydrogen or helium gas, gasoline was used as the buoyant material. During descent, air ballast tanks were filled with sea water, and for ascent, iron shot ballast was released. The pressure hull was made of drop-forged iron hemispheres, 2 m in inside diameter and 90 mm in thickness, allowing for two crew members. It was able to maneuver around the seafloor by thrusters driven by electric motors.

In 1952, he began building the famous bathyscaph *Trieste*. In 1958, *Trieste* was purchased by the Office of Naval Research (ONR) of USA and plans for Project Nekton started. The main purpose of Project Nekton was to reach the bottom of the Challenger Deep. On January 23, 1960 the Bathyscaph *Trieste*, piloted by Jacques Piccard and Don Walsh, made one successful dive to the depth of 10,913 m of the Challenger Deep. However, in considerations of the length of day, sea state, and stirred cloud of sediment, *Trieste* stayed at the bottom for only 20 min. No photographs of the sea floor were taken (Kohnen 2009).

During the same period, the French navy also took great interest in building a deep manned submersible. The objective of *Archimede* was to reach 11,000 m. By 1959, construction and engineering work on *Archimede* were fully engaged. The scientific history of *Archimede* was summarized by Alan Jamieson who suggested that the reports from *Archimede* were far more valuable at the time than was realized (Jamieson 2015). However, in its whole life, it did not fulfill its original mission to reach the Challenger Deep.

The main goal in the 1950s for most deep dives was to set record depths, whereas in the 1960s, after reaching the Challenger Deep in the Mariana Trench, the development of manned submersibles focused more on the solution of certain practical and scientific problems. Both the *Trieste* and *Archimede* submersibles are regarded as the first generation of deep submersibles to distinguish the other operational deep manned submersibles developed later.

In 1964, the second generation of deep manned submersibles began. Alvin was funded by the US Navy under the guidance of the Woods Hole Oceanographic Institution (WHOI). At first, its depth capability was only 1800 m. It was small enough to be able to put on board the R/V Lulu, which became its support ship. Instead of gasoline flotation, syntactic foam was used. Alvin had horizontal and vertical thrusters to maneuver freely in three dimensions. Scientific instruments, including manipulators, cameras, sonar and a navigation system, were installed. Three observation windows were available for the three crew members. In France, the two-person 3000 m-class

submersible Cyana was built. These two vehicles typified submersibles during the 1960s. In 1973, the original steel personnel sphere is replaced with a titanium sphere and more flotation is added, the depth capability of the Alvin has been increased to 4500 m. In the 1980s, 6000 m-class submersibles, such as the Nautil from France, the Sea Cliff of the US Navy, the Mir I and Mir II from Russia, and the Shinkai 6500 from Japan, were built (Kohnen 2009). In 2012, China successfully developed the deepest operational submersible “Jiaolong” (Cui 2013). They were theoretically able to cover more than 98% of the world’s ocean floor.

Hotta et al. (2001) had predicted the possibility of the third generation of deep manned submersibles. They defined that manned submersibles of the third generation would be capable of exceeding 10,000 m depth. Three possibilities were speculated. One possibility is a small and highly maneuverable one- or two-person submersible with a transparent acrylic or ceramic pressure hull. Two projects were funded by private sectors in 2005 and two full ocean depth solo manned submersibles “*Deepsea Challenge*” and “*Deepflight Challenger*” were constructed in 2011. In March 26, 2012, the movie director James Cameron took his privately built one-man submersible “*Deepsea Challenge*” 10,898 m down to the Challenger Deep in the Pacific Ocean’s Mariana Trench (<http://www.deepseachallenge.com/>). However, another project seemed to be a failure. Now USA, Japan, and China are developing full ocean depth three-person operational manned submersibles (Cui et al. 2014; Cui 2018).

Another possibility is a deep submergence laboratory, which would be able to carry several scientists and crew long distances and long durations without the assistance of a mother ship. This would be the realization of the dream like “*Nautilus*” in *20,000 Leagues Under The Sea* by French novelist Jules Verne. Strong scientific and/or social goals would be needed for such a submersible design to be pursued. Ohno et al. (2004) had carried out a design feasibility study, but up to now, there is no actual investment for this concept.

And there is a third possibility that the next generation will be evolutionary upgrades of existing second-generation submersibles. Hawkes (2009) had proposed some ideas on how to dramatically reduce the cost of manned submersibles which is one of the main criticisms to the application of manned submersibles.

Principles of Modern Manned Submersibles

There are several methods to submerge vehicles into the deep sea. The simplest way is to suspend a sphere by a cable, known as a bathysphere. However, mobility is lost and diving depth is greatly limited due to the self-weight of the cable. A second method relies on powerful thrusters to adjust vertical position in relatively shallow water. The submersible *DeepFlight Super Falcon* is a high-speed design which uses thrust power coupled with fins for motion control like the wings of a jet fighter (Hawkes 2009), Fig. 1. It descends and ascends obliquely in the water column at speeds up to 10 knots. Most submersibles employ a third method that, while using weak thrusters to control attitude and horizontal movement, relies principally on an adjustable buoyancy system for descent and ascent, see Fig. 2.

When on the surface, the submersible's air ballast tank is filled with air creating positive buoyancy; hence it floats. When the dive begins, air is vented from the ballast tank and filled with

sea water, thus creating negative buoyancy and sinking the vehicle. As the submersible dives deeper, buoyancy increases modestly due to the increasing water density created by the increasing pressure. Thus the submersible slows slightly as it dives deeper. When the submersible approaches the seafloor (50–100 m in altitude, i.e., height above the bottom), a portion of its ballast (usually lead or some other heavy material) is jettisoned to achieve neutral buoyancy. Perfect neutral buoyancy occurs when the positively buoyant materials (things which tend to float) on the submersible balance the negatively buoyant materials (things which tend to sink). This allows the vehicle to hover weightless in position and move freely about. As perfect neutral buoyancy is difficult to maintain, most submersibles have auxiliary weight-adjusting (trim and ballast) systems. This consists of a sea-water pumping system to draw in or expel water, thus adjusting the buoyancy of the submersible. Upon completing its mission, the remaining ballast is jettisoned and the submersible now with positive buoyancy begins ascending. When resurfaced, air from a high-pressure bottle is blown into the air ballast tank to give enough draft to the submersible for the recovery operation (Hotta et al. 2001).

In the development of the various submersibles, the most challenging equipment is the development of the FOD HOV since almost all of the technology challenges encountered in the development of unmanned submersibles are covered by the HOV. In the entry of submersible, the key technologies involved in the development of

Human Occupied Vehicle (HOV), Fig. 1 The future of manned submersibles could be the elegant *DeepFlight Super Falcon*. (Permission from Shanghai Rainbowfish Ocean Technology Co Ltd)

Human Occupied Vehicle (HOV), Fig. 2 Principle of descent and ascent for a modern deep submersible (Hotta et al. 2001)

the FOD HOV have been introduced and interested readers can read that entry.

Why Manned Submersible

There is no question that the manned submersible has earned its place in history. Much of what are now cataloged as new species were discovered in the last 30 years with the aid of submersibles. The ability to conduct marine science experiments in situ led to the development of intricate precision instruments, sampling devices for delicate invertebrates and gelatinous organisms that previously were only seen in blobs or pieces due to the primitive methods used to collect them (Askew 2001).

After the creation of unmanned submersibles in 1970s and 1980s, people have argued whether manned submersibles should be further developed (NRC 2004). Many people have thought that unmanned submersibles can replace all the functions of manned submersibles. However, after

about 30 years discussion, up to now, still many ocean scientists thought that manned submersibles have their own benefits.

First, the desire for personal accomplishment cannot be achieved in unmanned submersibles. For example, the great honor received by Jacques Piccard and Don Walsh in 1960 and James Cameron in 2012 when they dived to the Challenger Deep cannot be replaced. Second, beyond the desire for personal accomplishment, there are other reasons man should or could be included in an undersea work or exploration system. The poet, Dylan Thomas, has a line which reads "when all my five and country senses see." Man is a sensing creature possessing an integrated, coordinated, active intellect. When a man's trained intellect is part of a system, he is able to repair, reset, adjust, and adapt, and in short, to respond intelligently to the unusual situation. He can perform a variety of tasks because of his general orientation and versatility. The free-swimming diver comes closest to

Human Occupied Vehicle (HOV), Table 1 A comparison of efficiency of bottom time use. (Cited from a lecture PPT of Anatoly Sagalevitch at HAST, 2014)

Vehicle type	Searching of object after the bottoming	Sampling		High quality video	Measurements (physical, chemical)	Visual observation
		Simple (rock, single animal)	Complicated (fluid from smoker, slurp gun probe, etc.)			
HOV	<30 min	5–10 min	<30 min	100% continuous based on direct observation	100% trustworthy	100% direct
ROV	60–90 min	40–60 min	No experience: too complicated	20% of attempts during move of ROV	Open noisy data (thrusters)	30–40% on TV screen

exercising directly his senses in the ocean (primarily seeing, touching, and hearing). The man in the manned submersible, however, is sensing his environment remotely, except for one sense – that of sight. In the unmanned system all sense data is perceived remotely. Thus, this system is “remotely manned,” for man’s intellect and senses are still a part of the overall system, but they are applied remotely to the work site. Therefore, the primary reason for placing man at the scene is to make use of his active, interpretive ability to see (Talkington 1976).

There is no substitute for the autonomous, highly maneuverable submersible that can approach and collect without contact delicate zooplankton, while observing behavior and measuring the levels of bioluminescence, or probing brine pools and cold seep regions in the Gulf of Mexico for specialized collections of biological, geological, and geochemical samples. Tubeworms are routinely marked for growth rate studies and collected individually, along with other biological species that thrive in these chemosynthetic communities. Sediments and methane ice (gas hydrates) are also selectively retrieved for later analysis. Some new vehicles are still being produced, but have limited payloads, which restricts them to specific tasks such as underwater camera platforms or observation. Some are easily transportable but are small and restricted to one occupant; they can be carried by smaller support vessels and are more economical to operate. Man’s desire to explore the lakes,

oceans, and seas has not diminished. New technology will only enable, not reduce, the need for man’s presence in these hostile environments (Askew 2001).

When man is in the system, he must be protected from the hostile environment in a pressure hull. Since the pressure hull is usually made of steel, it becomes the largest, heaviest, and most costly part of a manned submersible. Anatoly Sagalevitch has made a comparison between HOV and ROV in Table 1 and he concluded that ROV is of only about 20% efficiency of bottom time use of the HOV. D.

Key Applications

Application Range of Each Type of Manned Submersibles

Manned submersibles have many uses worldwide, such as oceanography, underwater archaeology, ocean exploration, adventure, equipment testing, maintenance and recovery, and underwater videography. Manned submersibles basically have four types: ordinary manned submersible, DSRV, ADS, and rescue bell. Each type of submersibles have their own application ranges and they are introduced here.

The ordinary HOV can either be used for observations or taking samplings. Observations are made through three small viewports (one in front and one on each side), as well as with a number of video cameras coupled to multiple

in-hull monitors. In addition to a pair of manipulator arms, various scientific payloads may be attached to the front of HOV for collecting samples and performing experiments. Therefore, HOVs are powerful in carrying out all the deep sea observations and operations.

A DSRV is a type of HOV used for rescue of downed submarines and clandestine missions. In addition to the observational and operational capabilities of scientific HOVs, it also has the personnel transferability from a submarine to a DSRV. Rescue is usually accomplished by ferrying rescues from the stranded submarine to the pressure chamber of a DSRV.

Rescue bell is a simplified DSRV which does not have the maneuvering ability, but just ferrying rescues from the stranded submarine to the rescue bell.

An **atmospheric diving suit (ADS)** is a small one-person articulated submersible of anthropomorphic form which resembles a suit of armor, with elaborate pressure joints to allow articulation while maintaining an internal pressure of one atmosphere. The ADS can be used for deep dives of up to 700 m for many hours, and eliminates the majority of physiological dangers associated with deep diving; the occupant need not decompress, there is no need for special gas mixtures, and there is no danger of decompression sickness or nitrogen narcosis. Divers do not even need to be skilled swimmers (Thornton et al. 2012; Kesling 2011).

The ADS is the safest, most versatile deep diving system available for military and submarine rescue intervention use. It can be used for a wide variety of tasks in the full range of depth capability. These include but are not limited to (<http://www.oceanworks.com/our-business/military/military-ads/>): Search; Salvage; Aircraft crash site investigation and recovery; Test weapons Recovery; Submarine Emergency Ventilation and Decompression System (SEVDS) deployment; Emergency Life Support Stores pod posting; Acoustic and degaussing range service and inspection; Harbor and defense infrastructure inspection; DISSUB escape and rescue support; Equipment deployment and recovery; Mine countermeasures support.

Important Events of Manned Submersible Applications

Reaching the Challenger Deep

Manned submersibles reaching the Challenger Deep will always be an important event and up to now, only two manned submersibles have finished that feat. On January 23, 1960, the Bathyscaph *Trieste*, piloted by Jacques Piccard and Don Walsh, made one successful dive to the depth of 10,913 m of the Challenger Deep (Kohnen 2009). The movie director James Cameron funded a secret project to develop the full ocean depth solo manned submersible “*Deepsea Challenge*.” In March 26, 2012, he took his privately built one-man submersible 10,898 m down to the Challenger Deep in the Pacific Ocean’s Mariana Trench (<http://www.deepseachallenge.com/>).

Now, in United States, two full ocean depth manned submersibles (Deepsearch and Triton 36,000/3); in Japan, *Shinkai 12000*; and in China, two full ocean depth manned submersibles are under development (Cui 2018).

New Scientific Discovery

Between 1973 and 1974, project FAMOUS (French–American Mid-Ocean Undersea Study) was conducted in the Mid-Atlantic Ridge off the Azores using the French bathyscaph *Archimede* and the US submersible *Alvin*. The project was the first systematic and successful use of deep submersibles for science. They discovered and sampled fresh pillow lavas and lava flows at 3000 m

H

deep in the rift valley, where the oceanic crusts were being created, providing visual evidence of Plate Tectonics (WHOI 2018). In 1977, *Alvin* discovered a hydrothermal vent and vent animals in the East Pacific Rise off the Galapagos Islands at a depth of 2450 m. Discovery of these chemo-synthetic animals, which were not dependent on photosynthesis, had a profound impact on biology in the twentieth century, Fig. 3 (Corliss et al. 1979).

Salvage of H-Bomb

In 1966, the U.S. Navy called in *Alvin* to help find a hydrogen bomb accidentally dropped into the Mediterranean Sea. *Alvin* locates the bomb and, after the bomb skids down a slope on the first recovery attempt, it finds it again at a depth of 2,900 ft (880 m). Then, an unmanned torpedo recovery vehicle, CURV-I, became entangled in the weapon's parachute while attempting to attach a line to it. A decision was made to raise CURV and the weapon together to a depth of 100 ft (30 m), where divers attached cables to them. The bomb was brought to the surface by USS *Petrel*, Fig. 4.

Definition

A **hybrid remotely operated vehicle (HROV)**, also known as **autonomous and remotely operated vehicle (ARV)** is a latest innovation of unmanned **submersibles** which can combine the advantages of ROV technology and AUV technology to explore the oceans freely in a relatively large range and photo the seafloor in site with reliable interventions. Compared with traditional ROVs, the vehicle is self-powered while its tether is fiber-optical and finer with less restriction. A typical HROV consists of three major components: underwater vehicle, tether system, and surface support. The fiber-optical tether system and hybrid control architecture are notable features of HROVs.

Scientific Fundamentals

Historical Development

The concept of a light-tethered vehicle for 11,000 m operations appears to have been first proposed by James MacFarlane of International Submarine Engineering Company (ISE) in 1990 (McFarlane 1990). A little later, Japan Agency for Marine-Earth Science and Technology (JAMSTEC) developed first HROV “UROV7K” and a traditional ROV “Kaiko” which dived to

10,000.4 m depth in Mariana Trench in 1995 (Nakajoh et al. 1998).

While the Kaiko was lost for the accidental tether break between the vehicle and tether managing system (TMS) in 2003, new HROV “Nereus” was proposed to perform scientific research for full depth of the ocean (11,000 m) by Woods Hole Oceanographic Institution (WHOI) in USA (Webster and Bowen 2003). Early development is mainly focused on the fiber-optical tether and ceramic structure to insure the survivability in 11,000 m (Cooke 2005; Young et al. 2006). On May 31, 2009, the Nereus successfully completed its first dive to the hadal of Mariana Trench in 10,903 m at 11°22.1'N, 142°35.4'E (Bowen et al. 2010).

The Nereus employed twin free-flooded hulls to accommodate different modes (Fig. 1). In AUV mode, two independently articulated, actively controlled foils (wings) are located between the hulls at the aft and middle sections, respectively. AUV mode propulsion is provided by two 1 kW thrusters fixed on the aft tails and one 1 kW thruster on the articulated mid-foil. AUV mode has no lateral thruster actuation. The vehicle is hydrodynamically stable in pitch and heading when in forward flight. There is a downward-looking survey camera and several LED arrays

on the port hull. Additionally, a scanning sonar can collect high-resolution bathymetry of the seafloor. In ROV mode, the Nereus is configured with a work package containing a robot arm, sampling tools, sample containers, an additional high-resolution digital camera, two utility cameras, and several LED arrays. ROV mode propulsion is provided by two 1 kW thrusters fixed on the aft tails, as used in the AUV mode, with the addition of one lateral 1 kW thruster and one vertical 1 kW thruster (Bowen et al. 2009). In the past decade, many sea trials and applications were conducted to develop the Nereus. However, on May 10, 2014, the Nereus was unfortunately lost with 9,990 m depth in the Kermadec Trench near New Zealand. Then, its fragments appeared on the sea resulting from the ceramic spheres fracturing under high pressure of hadal ocean.

On the technical basis of HROV Nereus, WHOI put forward the solution to develop a new underwater vehicle, Nereid-UI, with the goal of deployment in polar ocean regions since 2011. The vehicle employs a lightweight fiber-optic tether enabling real-time control, high-resolution imaging, and immediate re-tasking over extended distances, thus freeing the vehicle from restrictions imposed by surface ice cover (Bowen et al. 2015).

Hybrid Remotely Operated Vehicle (HROV)/Autonomous and Remotely Operated Vehicle (ARV), Fig. 1 Nereus HROV, shown during its first sea trial in the Pacific in November 2007, is designed to operate in

AUV/ROV modes with 11,000 m depth. Left: the Nereus in AUV mode. Right: the Nereus in ROV mode (Bowen et al. 2009)

In addition, some other research institutes are committed to developing HROVs and the prototypes have been made. In 2010, the French National Oceanographic Institute (IFREMER) launched a development program of HROV for identified needs to explore and perform scientific intervention tasks in marine environments such as the cold water coral reefs, underwater canyons, seamounts, ridges, rift valley walls, and continental margins. IFREMER's new HROV "Ariane" (Fig. 2) targets precise mapping, sampling, and monitoring tasks through the implementation of a hybrid architecture to bridge between canonical ROV and AUV systems. The Ariane has two operational modes, tethered and autonomous, to allow operations from a light vessel without dynamic positioning (DP) capability. In March 2015, the Ariane successfully reached the ocean depth of 2,011 m (Brignone et al. 2015).

International appellation of HROV reflects innovative extension of traditional ROVs. Considering both AUV/ROV working modes, novel hybrid vehicles are also defined as ARVs. In recent years, China has become an important center for ARV research and development. Shenyang Institute of Automation (SIA) developed the first ARV in China to navigate under the Arctic ice in 2005 and participated in several Arctic scientific expeditions from 2008 to 2014

(Shuo et al. 2011). China Ship Scientific Research Center (CSSRC) developed a prototype of ARV "Seakite" in 2009 and upgraded the ARV for underwater applications in 2012 (Xu 2014). Under the funding of China's National Research and Development Projects, Shenyang Institute of Automation and Shanghai Jiaotong University launched their development of 11,000 m ARVs in 2016 individually, which will provide new available access to the hadal depth (Fig. 3).

Principles of Hybrid Remotely Operated Vehicle

As a self-powered vehicle, HROV can operate in two different modes. For range-free survey, the vehicle can operate untethered as autonomous underwater vehicle (AUV) capable of exploring and mapping the seafloor with sonars and cameras. For precise imaging and sampling, it can be converted at sea to become a tethered remotely operated vehicle (ROV). The ROV configuration incorporates a lightweight fiber-optic tether connected to the surface vessel for high bandwidth and real-time telemetry of video and data, enabling high-quality intervention and remote operation by a human pilot (Bowen et al. 2010).

The HROV system is composed of underwater vehicle, surface support module, and tether managing system (TMS). As the first step in an operational deployment, the surface support will launch the HROV and TMS into the water while keeping connection with the vessel through the armored tether. Once the vehicle and TMS have reached the desired depth, the vehicle will be released from the TMS. Then, the vehicle begins a free fall to the seafloor with light fiber-optic payout from the buffer of TMS. Once the vehicle has reached the bottom, the descent weight will be released from the vehicle and the neutrally buoyant HROV will then be free to cruise and conduct its mission. Once the HROV has completed its task on the seafloor, the fiber-optic can be cut off. The vehicle drops its ascent weight and returns autonomously to the surface. Once the vehicle is on the surface, put forward a recovery process (Bowen et al. 2009) (Fig. 4).

dive; 2-tethered survey/intervention; 3-autonomous survey (Bowen et al. 2009)

Why Hybrid Remotely Operated Vehicle

As well known, currently almost all the underwater interventions, especially robotic manipulation, are carried out by ROV technology. ROVs require a lot of support, including a surface vessel, where an experienced pilot (i.e., user expert) is able to operate the ROV by means of an umbilical cable. On the other hand, from the last 20 years, marine explorations in a large region promote AUV technology. The AUVs have some obvious advantages

over ROVs: no vessel, umbilical, or pilot is essential. However, it also presents a critical drawback that any kind of potential manipulation skill is impossible. Thus, HROVs try to join the best of both systems, ROVs and AUVs to explore the oceans freely in relatively large range and photo the seafloor in site with real-time intervention capability. Compared with a traditional ROV, the HROV is self-powered and its fiber-optical tether is finer with weaker restriction. HROVs provide

a flexible choice for marine scientists with real-time intervention (Garcia et al. 2016).

Key Technologies of HROV

Underwater Vehicle

The underwater vehicle is composed of main hull (frame), pressure housing, electronics unit, power supply, propulsion, control boards, environmental sensors, sampling tools, additional buoyancy, and so on. The overall design of HROV configuration is usually considered from several aspects to accommodate the hybrid modes: (1) the descent/floating performance between the surface and seafloor; (2) the maneuverability and low hydrodynamic drag in both operational modes; (3) the functions of environmental sensors and sampling tools. The design of the HROV frame has the characteristics of light weight without reducing rigidity and strength. Therefore, the choice of frame material is very important. The frame structure usually employs a single hull or twin hulls for good stability (Table 1). In addition, the application of buoyancy materials would provide enough buoyancy and pressure-resistance to guarantee safety of HROV in deep sea (Xu 2014).

Power and Propulsion

Power supply is closely related to the endurance of the vehicle. High density and reliability are very important for the power supply in use. Up to now, lithium-ion battery is the most common solution for its advantages of high density, long cycles, no memory effect, environmental pollution-free, etc. The application of lithium-ion batteries will greatly meet the development of deep-sea HROV with large depth, long time, small volume, and no gas precipitation.

Generally, 4 degrees of freedom (4-DOF) motion capability is essential to HROVs for fix-

point operation, including surge, sway, heave, and yaw. According to the motion DOF, fixed combinations of horizontal and vertical thrusters are configured for HROVs to increase vehicle maneuvering. In order to promote the mobility, special HROVs also designed rotary thrusters. The coupling/decoupling hydrodynamics, control of DOFs and rotatory sealing under high pressure are critical problems.

Light Fiber-Optic Tether

The key part of HROV system is a light fiber optic tether used when operated in ROV mode. Although the advantages of HROV including large range and high maneuverability, a light-weight cable is essential for intervention. The fiber optic tether just transmits high bandwidth data, except power supply. The main consideration of a fiber optic tether is the optimization among the reusability, economical efficiency, and feasibility. With the HROV system, the fiber optic is deployed at low tension between the vehicle and launch platform. As the vehicle moves in water, the tether is laid from the storage buffer, which decouples the hydrodynamics between the vehicle and surface. This decreases the drag propulsion of the vehicle and workload for the tether; hence the tether's size and weight can be minimized. The Sanmina/SCI tether was selected as the primary choice for the Nereus HROV and its characteristics are described in Table 2 (Webster and Bowen 2003).

Tether Managing System (TMS)

Compared with traditional ROVs and AUVs, the fiber-optic tether and TMS are obvious features of HROVs in hardware. According to special applications, the design of tether manage system is different. The following aspects must be considered carefully.

Hybrid Remotely Operated Vehicle (HROV)/Autonomous and Remotely Operated Vehicle (ARV), Table 1 Performance comparison of HROV configurations

Configuration	Descent/floating	Maneuverability	Sensors & tools
Single hull	★★★★	★★★★	★★
Twin hulls	★★★	★★★★	★★★★

Hybrid Remotely Operated Vehicle (HROV)/Autonomous and Remotely Operated Vehicle (ARV), Table 2 Sanmina/SCI fiber characteristics

Diameter (mm)	0.25
SG (fresh water)	1.36
Weight of 11 km in water (kg)	0.173
Working strength (N)	8
Breaking strength (N)	108

1. The influence of TMS on the moving flexibility of underwater vehicle should be considered, because it has a direct correlation with the payout of the optic-fiber. Active release by winch is feasible for the optic fiber in short distance. There are relatively few cables in disorder, and the storage of optical fiber is relatively easy. However, the finer release rate must match the speed of HROV. Otherwise, the transient strain between the vehicle and the tether will rip the fiber optic. Besides, the fiber optic should be uniform in diameter and have enough working strength. Another method of the payout of fiber optic is passively released by the drag force of vehicle. In this way, the fiber optic needs to overcome the adhesion stress (usually no more than 0.5 Kg) among the fibers in pack. Therefore, the passive release of fiber optic would not influence the motion of HROV.
2. Another consideration is surface influences of wave, current, and mother-ship movement. In order to minimize these influences, various buffer mechanisms are specially designed in the TMS. To the Nereus, the buffer device involved a snag-resistant depressor and a float pack to house the tether as shown in Fig. 5. The depressor was deployed far away from surface wave and current. The vehicle float pack contains the optical fiber dispenser, brake, fiber counter, and cutter. It floats above the vehicle, which is designed to minimize the drag and snagging possibility of the fiber on either the vehicle or sea floor. The depressor and float pack are mated together during launch process, protecting the fiber during the air-water transition. The depressor, float pack, and vehicle descend together to a designated depth. Once an

Hybrid Remotely Operated Vehicle (HROV)/Autonomous and Remotely Operated Vehicle (ARV), Fig. 5 The float-pack of Nereus separating from the depressor (Bowen et al. 2009)

appropriate depth has been reached, the vehicle and float pack separate from the depressor. As the vehicle and float pack descend, optical fiber pays out from both terminals. In other HROVs, a relay station or some repeaters are also used as buffer devices.

HROV Control System

The control of ROV implies a master/slave architecture and a qualified pilot. In recent years, AUVs are becoming more popular without the limitation of tether. However, at the same time, AUVs need more autonomy and the user has little possibility of intervention in case of sudden problems. So, as the combination of ROV and AUV, HROV is presented as a balanced option. The hybrid control architecture is another obvious feature of HROVs in software.

HROV control system has both remote and autonomous modes. The HROV control system can be divided into interconnected layers as followed. Concrete block diagram is shown in Fig. 6. On the surface, there is equivalent of a top-decision layer by operator in loop, which can intervene and monitor the behaviors of HROV online.

- Remote-control layer
Remote-control layer is surface remote monitoring console. HROV send related information to surface through the optical fiber communication, underwater acoustic modem,

Hybrid Remotely Operated Vehicle (HROV)/Autonomous and Remotely Operated Vehicle (ARV), Fig. 6 A kind of HROV control architecture (Xu 2014)

and surface radio as backup. The operators observe and analyze received data, and adjust its strategy online, take over motion control and other higher priority remote manipulation instruction, then send them to HROV through the communication link above.

- Self-perception layer

Self-perception layer mainly depends on various sensors integrated on HROV, such as navigation sensors, inspection sensors, and state monitor sensors. At the same time, perception layer also includes the understanding and processing of sensor data, and can transfer the understanding information to decision layer, then feedback the state information to self-control layer.

- Self-decision layer

Self-decision layer processes environment information output from perception layer, including global task management, extracts rational behaviors from behavior database to plan HROV navigation path, and then send instructions to self-control layer. To a certain context, self-decision layer is similar to preprogrammed AUV control, including simulation of mission programming, mission

implementation, mission download, and simulated running in deck preparation stage. It also takes real-time monitoring during underwater mission, automatic drive, obstacle avoidance, fault diagnosis and emergency treatment, data recording, and post-treatment in diving stage.

- Self-control layer

Self-control layer is related to internal state and environmental information measured by self-perception layer, which integrates control algorithms to get expected thrusts of the HROV, and transmits specific thrust instructions to executive layer, so as to achieve the planning objective. When surface remote layer is chosen to control HROV directly through the tether, it is working in ROV mode. When communication link is broken or removed, the vehicle will return to AUV mode automatically, and self-control layer will response independent instructions.

- Executive layer

Executive layer will allocate thrust instructions of self-control layer to each actuator, and drive the actuators to generate expected forces/moments needed.

H

Key Applications

Reaching the Challenger Deep

The goal of the Nereus is to provide the U.S. oceanographic community with the first capable and cost-effective vehicle for routine scientific survey, sea floor and water-column experimentation, and sampling to the full depth of the ocean in 11,000 m. On May 30, 2009, the Nereus successfully reached a depth of 10,903 m at 11 22.1'N, 142 34.4'E (Fletcher et al. 2009).

Scientific Research

Most of HROVs are used for scientific research. HROVs are superior to the traditional ROVs in economically efficiency, practicability and large range so as to be suitable in exploration and sampling of the seafloor. For example, the Nereus dived near the deepest known spot in the Challenger Deep, explored the edge of the sub

ducting plate, and took rock samples with its manipulator, which was fully operational. The vehicle then moved northwest across the trench floor toward the overriding plate, took tube cores and biological samples for approximately 2 km. Tube cores and biological samples were effectively collected (Fig. 7).

The goal to develop the Nereid-UI vehicle system is enabling real-time, detailed, close-range examination of biological and physical environments in glacial ice-tongues, ice-shelf margins. This approach will promote the existing capabilities for scientific operations under sea-ice, provided by conventionally tethered remotely operated vehicles, and autonomous underwater vehicles (Bowen et al. 2015).

Industry Applications

In addition to scientific research, HROVs can also be used in ocean engineering to solve complex

challenges of power station, water sewer, tunnel, and offshore industries.

Sabertooth HROV, developed by Saab Seaeye, broke a record for the longest tunnel inspection in 2014. During a round-trip of over 24 km, the Sabertooth collected real-time visual data while scanning the tunnel with its multi-beam sonar. The mission is to gather high-density dimensional data, discover open cracks or holes, find debris build-up, detect lining failures, and identify any rock falls. The Sabertooth can operate as either a remotely operated vehicle (ROV) with fiber-optic tether for real-time communication and pilot control, or as an autonomous underwater vehicle (AUV) to give flexibility in various tunnel inspection scenarios (www.saabseaeye.com) (Fig. 8).

Definition

Hydrodynamic design of a submersible is the prediction of hydrodynamic performance and shape optimization through theoretical analyses, numerical calculations, or/and physical experiments. The hydrodynamic calculation runs through all design stages of a submersible, but it is of significant importance during the concept design. Hydrodynamic coefficients and propulsion efficiency are the most important factors affecting the hydrodynamic performance which is one of key technical indicators of submersibles.

Scientific Fundamentals

Hydrodynamic Performance

In general, hydrodynamic performance for a submersible includes the performance of speed, maneuverability and seakeeping. They are closely related to the main elements, profile, general layout and navigation control of the submersible, and have an important impact on the safety, reliability, economy, and applicability of the submersible (Allmendinger 1990).

The speed performance is considered good when under the premise of meeting the speed indicators in the design task book, the power consumption of the host is low, or when the host power is selected, the speed that can be achieved is high. The speed performance consists of two

aspects, the resistance and the propulsion. A submersible working under water bears the gravity force, buoyance from fluid static pressure, thrust from propellers, and hydrodynamic force. The resistance is defined as the projection of hydrodynamic force in the opposite direction of the submersible's motion. An excellent shape can significantly reduce the resistance and help to save the energy. The resistance can be categorized into friction resistance, shape resistance, and appendage resistance. The friction resistance is proportional to wet surface area and can be easily calculated by using various empirical formulas of plate friction resistance. The shape resistance, which is also called viscous pressure resistance, is related to the profile of submersible and involves flow separation. It lacks effective approximate evaluation method for a general shape. The appendage resistance comes from the resistance caused by appendages of the submersible. Determining the appendage resistance is usually difficult, because it not only requires accurate resistance calculation of an appendage by itself but also needs to take into account the interaction between the main body and the appendages, and the interaction between appendages themselves.

The propulsion performance relies on the principles of design and application of submersible thrusters. Firstly, submersibles carry out various tasks such as marine exploration, salvage, and life-saving. Therefore, requirements of good maneuverability must be met. Secondly, high propulsion efficiency, not the maximum speed, should be achieved. This is to maximize the endurance and prolong the underwater operation time. The submersible has poor visibility when working in the deep sea, which makes underwater search operations more difficult. Increasing the endurance capability accordingly will undoubtedly increase the success rate of underwater operations. The displacement of submersible is generally designed to be very small, and the battery used as a power source is also very limited. It is important to improve the efficiency of propulsion and make effective use of valuable energy. It should also be further pointed out that the submersible uses a considerable percentage of energy

in the process of diving and floating, so even a slight improvement in propulsion efficiency can achieve a large increase in search area. This effect becomes more obvious as the diving depth increases. Thirdly, the weight of the propulsion should be reduced as much as possible. As mentioned above, the design displacement of the submersible is generally very small. However, the large diving depth requires a sharp increase in the thickness and weight of the pressure shell. Complex deep-sea operations also require the submersible to be equipped with a variety of instruments, which further increases the weight of the submersible. This creates a sharp contradiction. Therefore, it is of great significance to reduce the weight of the propulsion device so as to satisfy strength and mission requirements. The mainstream submersible thrusters are mainly the propeller type and water jet propulsion, and the propeller type propulsion mode is used most extensively. Apart from these types, in recent years the bionic propulsion has received increasing attention because of its high efficiency and low noise.

Maneuverability refers to the performance of a submersible to change or maintain its speed, attitude and direction through its control device. The meaning of maneuverability can be further divided into course retention under small rudder angle, course mobility under middle rudder angle, and emergency avoidance under large rudder angle. The main factors affecting maneuverability include principal scale, profile, position of center of gravity and floating center, and appendages. The analysis of maneuverability is based on the equation of motion, under premise that the hydrodynamic force acting on the submersible is known.

Last but not least, the seakeeping performance means that the structure still has sufficient stability and hull structural strength when it undergoes rocking motions, slamming, stall, or other phenomena due to external forces such as wind and waves, and can maintain a certain speed for safe navigation and operation. The seakeeping performance needs to be considered when the submersible moves or/and works near the free surface like a ship advancing or an offshore structure floating

on the free surface where the influence of waves cannot be ignored.

The hydrodynamic performance is only one of the many factors to be considered in submersible design. Other aspects such as structural analysis and man-machine-environment system also play important roles in the design. The method based on multidisciplinary design optimization (MDO) has become the most potential design method for large-scale complex engineering systems including submersibles. This method puts forward higher requirements for the accuracy and efficiency of its hydrodynamic performance prediction. Therefore, designers must pay attention to the research on the prediction method of hydrodynamic performance of submersibles.

Approaches for Hydrodynamic Forces/Coefficients

The determination of hydrodynamic forces/coefficients is important for predicting loads and induced motion analysis of submersible which will affect the design of submersible. Hydrodynamic forces acting on submersible can be divided into inertial hydrodynamic forces and viscous hydrodynamic forces. When the submersible is in steady motion, only viscous hydrodynamic forces need to be considered. When the submersible is in unsteady motion such as acceleration and deceleration, the influence of inertial forces or added mass should be taken into consideration.

Inertial hydrodynamic forces or added mass are usually estimated by empirical formula or evaluated in the framework of the potential flow theory which is based on the assumptions that the fluid is nonviscous, incompressible, and irrotational (Newman 2018). Following these, the governing equation is the Laplace equation instead of the Navier-Stokes equation. Added mass can also be determined by a planar mechanical machine or vibration tests. According to the potential flow theory, the added mass only depends on the shape of the submersible, having nothing to do with motion states of the structure.

Compared with inertial hydrodynamic forces, viscous hydrodynamic forces are more difficult to calculate. At present, there are four approaches to obtain viscous hydrodynamic forces, which are

constrained or self-propelled model test, system identification, approximate calculation method, and computational fluid dynamics (CFD) method. The model test can be carried out in a tank or wind tunnel and is most reliable. However, it is expensive, takes a long time, and has the problem of scale effect, and therefore not conducive to the development of low-cost submersibles. The method of system identification is suitable for the analysis of actual navigation data and the correction of hydrodynamic coefficients, which is not convenient to guide the maneuverability design of submersibles.

Approximate calculation method mainly refers to making some modifications based on the theoretical calculation formula for simple geometries. It can also refer to the semiempirical formula and charts which are sorted out from a large amount of model tests, rather than analytical solutions of the hydrodynamic model or equation systems. In the concept design stage, this method is effective because of the low requirement of calculation accuracy and is especially suitable for submersibles with a regular shape such as ellipsoids. A basic evaluation of hydrodynamic performance of the design model can be obtained, and it can provide the basis for the design of propulsion system and battery system if there are any. From the relevant research data and experience, although approximate calculation method has advantages of convenient use and fast evaluation, the scope of application is limited. It will produce large errors if it is not used properly.

With the continuous improvement of computer hardware and the rapid development of advanced numerical calculation technology, CFD method (Gao et al. 2016) can be directly applied to the design process of submersibles. Both commercial CFD software such as STARCCM+ and open source packages such as OpenFOAM are used to solve problems related not only to fluid dynamics but also fluid-structure interactions by combining with the finite element method. In the preliminary and detailed design stages, CFD method has been widely applied to evaluate resistance and viscous hydrodynamic coefficients. The accuracy depends on the selection of turbulence model, the mesh generation, and the setting of boundary

conditions. Because of difficulties in meshing and the limitation of computing time, it is still difficult to apply CFD method to shape optimization design.

Though CFD method has been widely used in the design process, there are still many technical problems to be solved. Different turbulence models or grid types often lead to different numerical results. In the absence of experimental data, it is difficult to judge the accuracy of the calculation results. Since the potential flow is solved by Laplace equation, and the Navier Stokes equation is solved by CFD numerically, a hybrid or multi-domain method has been developed for bodies floating or advancing on the free surface. In this method, a control surface is introduced to divide the whole fluid domain into subdomains (Chen and Liang 2016) and apply only potential flow theory solver in the external subdomain in which viscous effects can be ignored. This method may be easily extended to the study of submersibles since there is no need to consider wavy properties of the free surface. A reasonable way is to use these methods comprehensively according to their characteristics, either a coupling of physical experiments and numerical simulations or a coupling of different numerical methods and so on.

Key Applications

It is worth noting that submersibles with different functions have different requirements for hydrodynamic performance. Therefore, hydrodynamic problems to be focused depend on submersible types and missions. The following will describe the hydrodynamic problems in the design of autonomous underwater vehicle (AUV), human occupied vehicle (HOV), remotely operated vehicle (ROV), and autonomous remotely vehicle (ARV). The biologically inspired systems are gradually applied to design of submersibles (Kruusmaa 2018), though corresponding hydrodynamic problems are not illustrated here. The bioinspired submersible may become the submersible of the next generation, with radical designs not only on shape but also on propulsion system, control system, or other systems.

Hydrodynamic Problems in AUV

During the design process of AUV, designers need to study carefully and design its shape and hydrodynamic layout according to its hydrodynamic characteristics. The AUV hull provides space and watertightness for payloads and internal equipment, withstands pressure, and generates buoyancy. Meanwhile, external accessories such as tail fins and propeller are mounted on the hull. Hydrodynamic layout is also called maneuverability design which, through selection and layout design of fins, satisfies requirements of motion characteristics such as balance, motion stability, and maneuverability.

There are numerous AUV profiles, with the common ones shown in Fig. 1. Most AUVs adopt single axisymmetric rotating body shapes, especially the torpedo profile (Liu et al. 2002). From appearance they generally tend to be slender and have larger slenderness ratio and less resistance. The motion control is carried out by the propeller and fins arranged in stern. This kind of AUV has long voyage capability and ability to resist moderate currents. They are applicable to low precision detection tasks within larger regions. By contrast, non-axisymmetric shapes (Ura 2002; Kaiser et al. 2016) and multi-body AUV have better maneuverability and are suitable for a wider range of tasks though they have larger resistance.

An important hydrodynamic problem in AUV design is to investigate the influence of shape on its hydrodynamic performance. Experimental results of a symmetric series of 24 mathematically related streamlined bodies of revolution have even been reported (Gertler 1950), showing how the resistance of these bodies at deep submergence varies with changes in five selected geometrical parameters which are fineness ratio, prismatic coefficient, the nose radius, the tail radius, and the position of the maximum section. Many researchers have studied axisymmetric rotating bodies on above five parameters in order to further explore low drag shapes (Ericksen et al. 2001). Research on hydrodynamic performance and profiles of existing underwater vehicles mainly focus on axisymmetric rotating body shapes, while few open data are available on

non-axisymmetric shapes and multi-body AUV. These calculations or experimental data about axisymmetric rotating bodies mostly belong to submarine, torpedo, and other high-speed navigation bodies. The speed of AUV is lower and corresponding Reynolds number is smaller. Therefore, designers should be careful to use relevant data and conclusions.

With the growing maturity of AUV technology, its application field has been greatly expanded. The task-oriented design becomes the trend in order to adapt to wider demand for use. Submersible shapes must first meet specific tasks usage requirement. Non-axisymmetric or multi-body shapes will occupy an increasing proportion in future AUV designs so it is necessary to pay attention to the hydrodynamic research on these profiles.

Hydrodynamic Problems in HOV

The design of HOV is different from unmanned underwater vehicle (UUV). Its main dimensions and profile elements depend mainly on the sufficient layout space for person and equipment to be carried inside the hull. In the design of HOV, designers firstly start from layout requirement and consider other factors such as carrying capacity of the surface mothership, deployment, and recovery method, so that designers can calculate the main dimensions. Then designers make decisions on reasonable main elements according to the balance of gravity and buoyancy, requirements of resistance, propulsion, stability, and maneuverability.

Therefore, the shape of HOV has the following characteristics:

1. The body ship is short and thick, and the length width ratio L/B is small. The value of L/B at large depth is generally between 2 and 3, and the maximum value is not greater than 3.6 which is far lower than that of conventional submarines. The resistance performance of HOV is not good and speed is low.
2. The bow shape of HOV is complex and there are many appendages. In order to meet requirements of observation and operation, it is necessary to arrange sampling basket, operation

CR-02 (torpedo shape)

Seaglider (Low-drag shape)

PTEROA (flat shape)

Sentry (vertical flat shape)

SeaBED (two-body shape, www.whoi.edu)ABE (multi-body shape, www.whoi.edu)

manipulator, camera, and other equipment in the bow of HOV. Appropriate space should be reserved for the observation window of HOV.

3. The bottom of HOV is usually flat. This is not only to meet requirements of sitting on the bottom but also convenient to arrange larger equipment such as battery and ballast.

In the design of HOV profiles, designers can only optimize the local shapes or appendage shape to reduce the resistance and meet the hydrodynamic performance. In order to carry out this work, it is necessary to analyze details of the flow field around the HOV to find the location of flow separation. Then, the local shape or appendage shape which leads to flow separation is modified. Finally, the modified scheme is verified to confirm whether it can improve hydrodynamic performances.

Due to the limitation of weight and volume, the energy carried by HOV at large depth is limited, so it cannot be used in the movement of diving from the sea surface to several thousand meter below or returning to the surface from several thousand meters below. The movement that does not use energy is called unpowered diving and floating. Because the total residence time of HOV is limited, the speed of diving and floating will directly affect the working time of HOV on the seabed. In the process of unpowered diving and floating motion design, it is necessary to ensure both the stability and the speed of unpowered diving and floating (Ma and Cui 2004). The stability of HOV during the unpowered diving and floating is generally guaranteed by stabilizing fins. When designing the stabilizing fins, the stability of the horizontal plane can be improved on the premise of ensuring that of the vertical plane.

In order to ensure the speed of unpowered diving and floating, it is necessary to design a suitable weight of disposable ballast to make the HOV produces negative or positive buoyancy. If the diving speed is too fast, it will easily lead to accidents such as touching the bottom, and if the speed is too slow, the underwater operation time will be affected. Therefore, it is necessary to accurately calculate the weight of the ballast that can

be dropped. It is of importance to establish the hydrodynamic model of HOV to predict its trajectory and attitude under certain conditions.

Hydrodynamic Problems in ROV/ARV

ROV is a kind of underwater vehicle with wired remote control, which is the most widely used type of submersible. ARV synthesizes the advantage of AUV and ROV, and it has its own energy and connects with the mothership through optical fiber cable. It can realize medium range search and fixed-point observation in autonomous, remote control, and monitoring mode in deep-sea environment.

Compared with other types of submersibles, ROV and ARV have cables connected to the surface mothership when they work, so they are not only affected by ocean currents but also disturbed by underwater cables. The surface mothership and the part near the free surface of the cable are affected by wind, waves, and currents; the underwater part of the cable, the submersible, or the relay station are also inevitably affected by the ocean current and internal waves; there are very complex interactions among the surface mothership, the cable, the submersible, or/and the relay station, which constitute a complex dynamic response system. Therefore, in the design process of cable submersible, it is necessary to carry out numerical simulations on the motion of submersibles to understand its dynamic response characteristics. The reliability and safety of equipment can be guaranteed by effective control of cable and submersible.

In the research of ROV and ARV motion simulations, underwater cable modeling is a key work. Because the motion of underwater cable is generally nonlinear and the hydrodynamic force acting on it is time-varying, the dynamic problem of underwater cable can only be solved by numerical approaches. The lumped mass method and finite difference method are the most widely used (Feng and Allen 2004). After the hydrodynamic modeling of cable and submersible is completed, the dynamic motion analysis of the whole system can be carried out, and the maneuverability and control performance of the submersible can be studied.

Definition

Hydrodynamics is the study of liquids in motion and their interaction with a solid object [https://en.wikipedia.org/wiki/Fluid_mechanics]. This subject compares to hydrostatics, which is about fluid at rest. Along with aerodynamics, hydrodynamics is one of several subdisciplines of fluid dynamics.

Subsea systems are submerged-undersea structures, typically without direct impact from the free surface of the ocean (Bai and Bai 2019) except during installation. The subsea systems are enormously diverse. For instance, in offshore oil and gas engineering, subsea systems include the following:

- Structures associated with drilling systems, including wellheads, BOPs, and drilling risers.
- Manifolds and other support structures for containing and protecting valves, tees, flanges, or mechanical connectors. These structures typically have a foundation to enable the seabed soil to support the system, a functional element containing pipes valves or other hydrocarbon-containing components, and a protective frame that prevents damage to the structure from fishing gear or dropped objects.

Hydrodynamic Performance

- [Hydrodynamic Design](#)

- Pipelines, which include flexible flow lines, rigid steel pipelines coated in concrete or polymeric coatings, umbilicals, and cables (Griffiths et al. 2018).

Here, the subsea systems contrast to the topsides above the waterline. More widely, the subsea systems are used to describe, for instance, gliders in oceanography, submarines in maritime engineering, or remotely operated vehicle (ROVs) and communication cables in other domains of ocean engineering [[https://en.wikipedia.org/wiki/TopsidesandSubsea_\(technology\)](https://en.wikipedia.org/wiki/TopsidesandSubsea_(technology))].

Hydrodynamics engineering in subsea systems, underlining practical application, has evolved to focus on understanding water motion to support subsea structural engineering by defining the loads experienced by subsea systems.

Introduction

Hydrodynamic engineers calculate forces and moments induced by water in motion for a safe and efficient subsea system, just like engineers consider wind loads on bridges or aircraft. Challengingly, water is over 830 times denser than air. The loads on the same object generated by moving water can be more significant than moving air at a similar speed. Conversely, objects moving through water or water moving past objects tend to occur at greatly reduced velocities than those dealt with in aeronautics. The comparative nondimensional behavior of these fluids can be understood by considering the Reynolds number of the flow, which defines the ratio of inertial to viscous forces. Reynolds number is defined as $Re = VD/\nu$ where V is the fluid velocity (or object in a still fluid), D is the characteristic length of the object, and ν is the kinematic viscosity. The typical ocean flows around subsea systems produce Reynolds number values in the range 10^4 to 10^6 , which means that the flow and wake produced are often turbulent.

Ocean water also frequently moves back and forth due to wave and tides, and this oscillatory motion may create an additional challenge to the subsea system. These oscillatory flows can be understood using the nondimensional Keulegan-

Carpenter parameter defined as $KC = U_{\max} \cdot T/D$ where in this context $U_{\max}$ is defined as the peak oscillatory velocity and T the period of the oscillation according to $U(t) = U_{\max} \cdot \sin(2\pi t/T)$.

Many subsea systems reside on the seabed once installed, such as oil and gas pipelines and communications/power cables. In contrast to the intention, they may move subject to seabed scour and erosion. The local scour around a subsea system is another area that hydrodynamics has contributed to significantly.

Over the years, the study of subsea system hydrodynamics has received contributions from many mathematician and engineers not necessarily working on subsea systems. Sarpkaya et al. (1982) and Barltrop and Adams (2013) provided excellent documentation of the principals and design methods. Theoretical analysis, field measurements, laboratory experiment, and computational simulation have become three main approaches in hydrodynamics study in recent years. In particular, computational fluid dynamics (CFD) has been widely used in hydrodynamics for subsea systems. In the era of aviation and space exploration (aerodynamics engineering), hydrodynamics has benefited from theoretical and technological advancement in that field, in parallel with the ongoing improvements in computational capabilities following Moore's law [<https://www.investopedia.com/terms/m/moorelaw.asp>].

Dynamic Interaction

The water-induced forces (F) and moments (M) on a subsea system are dependent on the velocity (u) and pressure (p) field of the fluid near the fluid-structure interface. The force can be expressed as

$$\mathbf{F} = \oint_A p d\mathbf{A} + \mu \oint_A \frac{d\mathbf{u}}{dn} dA \quad (1)$$

where μ is the fluid viscosity, du/dn represents the normal velocity gradient on the structure surface, and A is the fluid and structure interface area. Here, the first term is the pressure force, whereas the second term is the friction force. Despite its

simple form, the difficulty in calculating the force arises when the pressure and velocity are not spatiotemporal invariant. Due to the viscosity, water and the subsea system's interaction are a dynamic one in many practical applications. Water viscosity creates a boundary layer adjacent to a solid surface in relative motion. The boundary layer flow is the source of vortex generation and shedding from the solid surface. This vortex shedding process leads to a dynamic change in velocity and pressure adjacent to the solid surface and, therefore, a dynamic force on the solid surface. The following Fig. 1 shows such a dynamic process, where many counterrotating vortices are generated in the wake of an oscillatory cylinder immersed in a steady current.

Study Approaches

Since Daniel Bernoulli (1700–1782), mathematical analysis and laboratory experiment have been two major approaches in

hydrodynamics study (Darrigol 2005). Many theories are the foundation of fluid dynamics, including Bernoulli's principle and the Navier-Stokes equations. In particular, the Navier-Stokes equations' derivation is recognized by many, if not all, as the pinnacle of fluid dynamics. The Navier-Stokes equations mathematically describe Newtonian fluids' motion through a series of partial differential equations expressing the conservation of momentum and conservation of mass [https://en.wikipedia.org/wiki/Navier-Stokes_equations].

A very common hydrodynamics model with a great deal of utility at adequate but imperfect accuracy is the set of equations known ubiquitously as Morison's equations, albeit first published in a paper also coauthored by O'Brien, Johnson, and Schaaf (Morison et al. 1950). These equations give the hydrodynamic forces on elongate structures such as piles, oil and gas platform jacket legs and braces, and subsea pipelines as follows:

H

Hydrodynamics for Subsea Systems, Fig. 1 The water flow field adjacent to a solid bluff body can be a dynamic one, which induces a time-dependent force on the cylinder. The top shows the flow field from a computer simulation, with the undisturbed incoming flow in the horizontal direction from left to right while the cylinder oscillates in the

vertical direction. The time-varying signal at the bottom is the drag force on the cylinder (in the same direction of the flow), with the red dot indicating the force induced by the instantaneous flow field on the top (from unpublished work)

$$F_Y(t) = 0.5 \rho \cdot D \cdot C_Y \cdot |U_c + U_w(t)| \cdot (U_c + U_w(t)) \\ + \frac{\pi \cdot D^2}{4} \rho \cdot C_M \cdot a_w(t)$$

$$F_Z(t) = 0.5 \rho \cdot D \cdot C_z \cdot (U_c + U_w(t))^2$$

where $F_Y(t)$ are the time-varying forces orthogonal to the structure axis and in line with the flow, $F_Z(t)$ are the forces orthogonal to the flow and the structure axis (representing the lift force for subsea pipelines), ρ is the liquid density, C_Y is the “drag” coefficient, U_c is the steady component of the liquid flow velocity, $U_w(t)$ is the time-varying wave velocity, C_M is the “inertia” coefficient, $a_w(t)$ is the acceleration of the fluid, and C_z is the “lift” coefficient. Note that this formulation ignores any time-varying forces on the structure due to vortex shedding.

Today, computational fluid dynamics (CFD) has become a valuable tool in almost all fields of fluid dynamics, including hydrodynamics for subsea systems (Tong et al. 2017). One simple reason is mathematicians have not yet found a universal solution to the Navier-Stokes equations. Instead, to obtain the fluid velocity and pressure adjacent to a solid object through Navier-Stokes equations, the only way is to apply a discretization method so that they are solvable by a computer algorithm, i.e., computational fluid dynamics. This tool is potent as it can reveal the flow field at any point of interest in one simulation. The method is highly repeatable, and the construction of a CFD simulation usually is significantly cheaper than the construction of laboratory tests. However, caution should be given to validate the CFD simulations (Fig. 2).

Applications

Many challenges in subsea engineering have a hydrodynamic element. Here, we give some examples.

Vortex-Induced Vibrations

Recall that vortex shedding from a subsea structure may create a time-varying periodic force

(Zhao et al. 2012). When the frequency of vortex shedding matches or is close to that structure’s natural frequency, the so-called vortex-induced vibration (VIV) may occur – a resonant response of the structure to the period force induced by the fluid (Bearman 1984). VIV is a significant part of the design of subsea systems for two reasons: (1) Excessive stress as a result of vibration may directly damage a subsea system, and (2) even without harmful stress, the periodic motion over millions of cycles can cause fatigue to a subsea system.

To put this into perspective, assuming a cylindrical steel structure has a diameter D of 1 m subject to 1 m/s ocean current (u) when vortex shedding frequency (f) matches its natural frequency (f_n). If this ocean condition happens 10 days per annum, how many cycles of vortex-induced vibrations the subsea system in a design life of 30 years might experience? First, let’s assume the Strouhal number (S_r) is 0.2 for this subsea system at the metocean condition, so

$$S_r = \frac{fD}{u}. \quad (2)$$

Thus $f = 0.2$ Hz by submitting the velocity and diameter into the equation. The number (N) of vortex-induced vibrations of the structure under the single ocean condition is $N = 30 \text{ years} \times 10 \text{ days/year} \times 86,400 \text{ s/day} \times f = 5.18 \text{ million}$. Here the stress due to a single cycle of vibration may be inconsequential; however, bending a steel pipe back and forth for 5.18 million times certainly is not an impact that can typically be neglected. This is one of the reasons why VIV is a significant consideration in the design of subsea systems.

Flow-Induced Scour

Soil and sediment’s movement in the vicinity of a subsea structure – flow-induced scour – is another traditional area of interest for hydrodynamics (Soulsby 1997; Sumer and Fredsøe 2002). The issue arises that a bed-seated subsea system tends to redistribute fluid velocity around it (Zhao et al. 2010), which would locally increase

H

Hydrodynamics for Subsea Systems, Fig. 2 The computational fluid dynamics (CFD) simulation of the flow around a pipeline partially embedded in a seabed. The pipeline is nonuniform, with a smaller diameter in the middle part. The pipeline is colored by the fluid's pressure distribution, where red indicates high pressure and blue

indicates low pressure. The velocity field is shown by streamlines generated uniformly at specific points upstream but has concentrated to the central part on arrival. The mesh used in discretization for the Navier-Stokes equations is shown in blue at the far top-left corner on a plane perpendicularly cutting through the pipeline

the friction force (bed shear stress) on the seabed. Then, depending on the local soil and sediment characteristics, scour may happen around the structure. This process would typically result in a local scour pit due to the loss of soil and sediment, leading to the structure's stability issue. Such a feature is better known in rivers (Soulsby 1997), such as around a bridge pier, where a scour pit could be seen at the foot of a pier after flood water recedes. In the marine environment, tidal current- and wave-induced scour are common in nearshore areas from shallow to deep waters, and hydrodynamics has been a valuable tool in studying and preventing it.

Oscillatory Flow

It is not hard to imagine why water can move in an oscillatory trajectory. Still, this common flow in the ocean behaves distinctively different with that of a unidirectional flow around a subsea structure (Tong et al. 2015b). A periodic varying velocity characterizes oscillatory flow. The oscillatory-flow hydrodynamics depend on both the Reynolds number (Re , defined in a similar way as in unidirectional flow) and an additional parameter – Keulegan-Carpenter (KC) number. The KC number is related to the oscillatory flow period and represents the ratio of orbital distance compared to a subsea structure's characteristic length. For a

classic cylindrical bluff body, the vortex-shedding regimes induced by a sinusoidal oscillatory flow show a great diversity compared to the field generated by the steady incoming flow. Due to the acceleration of the water particles, oscillatory flow introduces a new force term on a subsea structure, which is inertia force. Besides, the oscillatory flow may induce vibrations to subsea systems by itself. When KC is large – the wave in a period travels a much longer distance than the size of a structure – the impact of oscillatory flow, however, is similar to that of the steady directional flow.

Modeling of Hydrodynamic Forces on Complex Structures

Many subsea structures contain many tubular members, all at different angles and often oriented so that the flow must go past multiple in-line members – as illustrated for a cross section through a typical offshore jacket as shown in Fig. 3. The incoming flow passes through the structure between the members, and some of the flow diverts around the structure due to the increased resistance of flow passing through the structure (Tong et al. 2015a, b). However, this diverted flow means that individual member sees a reduced flow velocity and reduced hydrodynamic forces due to the collective effects of the

group of members. To account for this reduction in local flow, simplified analytical estimates of the local flow reduction have been developed to improve upon the prediction of hydrodynamic forces using Morison's equations (see Taylor et al. (2013)).

These same principles can also be applied to very different scenarios of interest outside the oil and gas industry, for example, to predict the available energy that can be captured from an array of tidal turbines placed in a channel that experiences strong and predictable tidal flows. The influence of the turbines on each other and the overall influence of the farm of turbines on the flow through the channel can be captured using this approach. See, for example, (Adcock et al. 2013, 2021).

Biomimetic Design

A functional subsea system through biomimetic design is still rare, but like biologically inspired designs in other areas, it has a bright future in the subsea systems, especially for unmanned vehicles (Chu et al. 2012), such as remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs). Through comparison hydrodynamics studies, the idea is to improve the underwater vehicles' maneuver efficiency to let them behave like aquatic animals.

Hydrodynamics for Subsea Systems, Fig. 3 Sketch of a cross section through a typical offshore jacket showing flow passing through and around the structure as a group of elements

Definition

Hydroelasticity was first defined by Heller and Abramson (1959), who stated that “it is concerned with the phenomena involving mutual interactions among inertial, hydrodynamic and elastic forces.” Theoretically, the fluid pressure acting on a structure will cause rigid body motion and structural deformation, and rigid body motion and structural deformation will interfere with the surrounding flow field. Hence, fluid-structure interaction problems can be considered hydroelastic problems. However, compared with rigid body motion, the deformation of traditional offshore

structures, such as ships and platforms, is very small. The influence of deformation on the flow field can be ignored. Thus, when calculating the surface pressure, the structure can be regarded as a rigid body. According to structural analysis, the structure is regarded as a deformable body, and structural deformation is caused by fluid pressure. Therefore, hydroelasticity can be decoupled into a hydrodynamic problem and a structural analysis problem (Cui 2007).

Scientific Fundamentals

Historical Development Under Homogeneous Sea Conditions

Linear Hydroelastic Theories

Based on the “dry hull” modal analysis theory and strip theory, Bishop and Price (1979) established the well-known hydroelastic theory of ships. The hydrodynamic force of the ship is calculated by strip theory, as shown in Fig. 1, and the hydrodynamic force and structural damping are considered external effects on the “dry hull.”

Based on this theory, Bishop et al. (1978) and Belik et al. (1980) simulated the slamming response of elastic hulls in irregular waves. Dong et al. (1989) and Dong and Lin (1992) analyzed the hydroelastic response of a shallow draft ship based on linear hydroelastic theory and

compared the numerical calculation results with the results of sectional ship model tests. Aksu and Bishop (1991) simulated the bending moment and shear response of a ballast oil tanker sailing in irregular long-peak waves in the time domain under three loading conditions. Zhong and Zhao (1998) studied the effects of wavelength and forward speed on the natural frequency and wave-induced responses. Bereznitski (2001) considered the ship as a rigid body and an elastic body and calculated its bottom-slamming response. Through a 2D experiment, Liu et al. (2001) studied the elastic deformation and mooring force of a large-scale floating structure under regular waves.

Although various two-dimensional hydroelastic methods have been widely used in practical engineering problems, their basic assumptions ignore the mutual interference of fluid motion along the length direction; therefore, they cannot solve the hydroelastic problems of marine structures with obvious three-dimensional characteristics. Wu (1984) and Price and Wu (1985) presented a general three-dimensional hydroelastic theory for a flexible body with an arbitrary shape traveling through or stationary in waves. Compared with two-dimensional hydroelastic theory, three-dimensional hydroelastic theory can effectively solve the fluid-structure interaction of arbitrarily shaped objects and can fully reflect the influence of the three-dimensional characteristics of the structure on the flow field.

Hydroelasticity Theory,

Fig. 1 Diagram of a strip-theory implement (McLain and Rock 1996)

Du (1996) established a complete frequency-domain analytical method of the 3D hydroelastic response theory. Wang (1996), who employed the time-domain Green function, developed a linear three-dimensional, time-domain, hydroelastic theory. Wu (1984) and Wu and Price (1985) derived a generalized interface boundary condition of flexible structures. A general linear boundary condition for the hydroelasticity of arbitrarily shaped structures was produced by Xia and Wu (1993). Based on the 2.5-D fluid method (Zhao and Aarsnes 1995), Hermundstad (1995) reported a linear hydroelastic theory for ships moving at a high forward speed. Malenica et al. (2003) analyzed the symmetric hydroelastic response of barges under shock waves and linear waves by using the inhomogeneous Timoshenko beam model and three-dimensional boundary integral method. Chen et al. (2005) analyzed the hydroelastic response of elastic offshore structures in regular waves based on three-dimensional linear hydroelastic theory, as shown in Fig. 2. The predicted vertical displacement along the structure agreed well with the experimental data, as shown in Fig. 3.

Nonlinear Hydroelastic Theories

The above research on the hydroelastic response is only applicable to the case of microwaves and the case of small amplitude motion and ship deformation. However, when the ship is sailing in

waves, it can be found that the wave load and motion present obvious nonlinear characteristics.

Based on perturbation theory, Jensen (1978) developed the nonlinear quadratic strip theory, which can consider the influence of nonlinear wave excitation forces on the motion response of a floating body. Jensen and Dogliani (1996) extended nonlinear quadratic theory (Jensen 1978) to predict the response of container ships to continuous wave excitation. Their results showed that the nonlinear response caused by the wave-induced vibration was equivalent to the linear response for the wave with a small average zero-crossing period; therefore, the nonlinear effect must be considered; for the long-peak wave, the nonlinear effect cannot be considered.

Based on the higher-order differential relationship between relative velocity and the corresponding hydrodynamic force established by Soding (1982), Xia and Wang (1997) derived a differential form, the hydroelastic equation, which can take into account the nonlinear hydrodynamic effects caused by bow drift, and they predicted the hull response in irregular waves, which was in good agreement with experimental results. Based on the two-dimensional potential flow theory, Xia et al. (1998) derived a two-dimensional, time-domain, strip hydroelastic theory, which can take into account the effects of nonlinear hydrostatic-restoring forces and nonlinear F-K forces. Park and Temarel (2007)

Hydroelasticity Theory, Fig. 2 Schematic outline of a model structure (Chen et al. 2005)

Hydroelasticity Theory, Fig. 3 Vertical displacements along the length under regular waves (Chen et al. 2005)

proposed a two-dimensional, nonlinear hydroelastic analytical method that can simultaneously take into account the nonlinear effects of radiation forces, F-K forces, and hydrostatic-restoring forces.

Wu and Moan (1996) and Wu and Hermundstad (2002) established a nonlinear hydroelastic analytical method for ship hulls under nonlinear vertical loads. In this method, the influence of the nonlinear vertical load is divided into a linear part and a residual part (nonlinear correction term). The linear part can be predicted by 2D, 2.5-D, or 3D potential flow theory; the residual part includes convolution of the time-delay function and nonlinear correction force due to slamming. Based on the fully coupled, three-dimensional, finite-element, structural model and three-dimensional, boundary-element, hydrodynamic model, Malenica and Tuitman (2008) proposed a generalized hydroelastic model that can analyze wave-induced vibrations and flutters of container ships in the frequency and time domains.

For second-order, nonlinear wave loads, Wu et al. (1997) first considered the influence of the nonlinear second-order, hydrodynamic load on

the response of a floating body caused by the rotation of a rigid body and the change in the free instantaneous wet surface and proposed the three-dimensional, nonlinear hydroelastic theory. Based on this theory, Chen (2001) deduced the generalized form of the second-order, hydrodynamic coefficients of the sum frequency and difference frequency of the floating body and the generalized form of the hydrodynamic force of the anchored floating body and established the three-dimensional, nonlinear frequency domain, hydroelastic motion equation of the anchored floating body. Based on the pressure integral method, Maeda et al. (1997) and Ikoma et al. (2000) simplified the floating body as an elastic plate and studied the influence of the second-order, wave load of difference frequency acting on the very large floating structure (VLFS) on the vertical displacement of the floating body by using thin plate hydrodynamics. For a floating body with a large deformation, the influence of the membrane force of the plate on the elastic response of the floating body should be considered. Chen et al. (2003a, b) established a frequency-domain and time-domain hydroelastic method that can consider both fluid and structural

Hydroelasticity Theory, Table 1 Particulars of the plate by Chen et al. (2003a)

Poisson's ratio ν	0.13	
Mass density ρ_b	256.25	kg/m ³

nonlinearity. The key parameters of the structure are listed in Table 1. Taking the motion and deformation of a large deformation-floating flat plate in multiple regular waves as an example, the influence of membrane forces on structural deformation and stress was discussed, as shown in Fig. 4.

Analytical Method Under Homogeneous Sea Conditions

Linear Hydroelastic Theories

According to the linear problem, the following assumptions are made:

1. The amplitude of the surface wave is assumed to be small in comparison to its wavelength.
2. The motions and distortions of the structure are assumed to be small and continuous.
3. The material is assumed to be linear.

Based on these assumptions, the linear hydroelastic problem can be solved through the frequency-domain method and time-domain problem, and the time-domain method can be transformed into the frequency-domain method by Fourier transform or Laplace transform.

Frequency-Domain Method The equation of hydroelasticity in the frequency domain can be written as

$$[-\omega^2(a + A) + i\omega(b + B) + (c + C + \Delta C)]p = F_w \quad (1)$$

where the response is assumed to be sinusoidal with the same frequency as the excitation, where

- $\{a\}$ is the symmetric inertial matrix of the dry hull.
- $\{A\}$ is the added-mass matrix.
- $\{b\}$ is the structural-damping matrix.
- $\{B\}$ is the hydrodynamic-damping matrix.
- $\{c\}$ is the diagonal stiffness matrix of the dry hull.
- $\{C\}$ is the fluid-restoring or stiffness matrix.
- $\{\Delta C\}$ is the additional restoring matrix from the linear external actions such as mooring lines.
- $\{p\}$ is the column matrix of the principal coordinates.
- $\{F_w\}$ is the wave excitation matrix including the Froude-Krylov and diffraction forces.

In addition to the elastic deformation of the structure, the largest difference between the seakeeping quality and hydroelasticity is the effect of deformation on the flow field. In potential flow theory, this effect is mainly reflected in the difference in radiation potential.

1. For seakeeping quality, the radiation potential ϕ_R is caused by rigid body motions (six degrees of freedom).

$$\phi_R = \sum_{r=1}^6 \varphi_r \dot{p}_r$$

where φ_r is the normalized velocity potential; and $\dot{p}_r$ is the principal coordinates. The dot sign represents differentiation with respect to time.

2. For the hydroelasticity, the radiation potential ϕ_R is caused by rigid body motion and elastic deformation (6 + N degrees of freedom).

$$\phi_R = \sum_{r=1}^{\infty} \varphi_r \dot{p}_r$$

The radiation force consists of two parts. One is proportional to acceleration, and the proportional coefficient is called the added mass $\{A\}$; and the other is proportional to velocity, and the proportional coefficient is called the damping coefficient $\{B\}$.

Hydroelasticity Theory, Fig. 4 Different contributions of bending moments, M_y in Chen et al. (2003a)

Time-Domain Method For the linear time-domain problem, the superposition method can be used.

$$\begin{aligned}
 (a + A')\ddot{p}(t) + b\dot{p}(t) + \int_0^t H(t - \tau)\dot{p}(\tau)d\tau \\
 + (c + C + \Delta C)p(t) \\
 = F_w + F_c
 \end{aligned} \quad (2)$$

where $A' = A(\omega) + \frac{1}{\omega} \int_{-\infty}^{\infty} H(t) \sin(\omega t) dt$; $H(t) = \frac{2}{\pi} \int_0^{\infty} [B(\omega) \cos(\omega t)] d\omega$; and F_c is the column vector of the generalized concentrated force.

Nonlinear Hydroelastic Theories

Transient phenomena observed in the hydroelasticity of ships and other floating structures can only be studied in the time domain. The nonlinearity of hydroelasticity may come from the nonlinear excitation force and nonlinear structure.

1. Nonlinear Excitation Forces

This may be caused by whipping induced by ship slamming or underwater explosions, dynamic capsizing, collision and grounding, cobblestone oscillation (Cui 2007), moving loads, mooring forces, etc.

2. Nonlinear Structure

This may be caused by nonlinear structural materials, nonlinear mooring systems, nonlinear connectors, etc.

The nonlinear hydroelastic problem can be expressed as

$$[M]\ddot{x} + [C]\dot{x} + [K]x = F \quad (3)$$

where $[M]$, $[C]$, and $[K]$ are the generalized mass, damping coefficient, and stiffness matrices, respectively; F is the generalized force vector, usually consisting of concentrated forces, such as mooring forces and landing forces of aircraft, and distributional fluid forces on the wetted surface of the body; and $\{x\}$ is a vector (column matrix) of generalized coordinates.

Hydroelasticity Under Inhomogeneous Sea Conditions

The above discussions about hydroelasticity are all relevant to homogeneous sea conditions. For an ultralarge floating body, coastline, or island reef constructed near the shore or near the island reef, the seabed topography will change, and the homogeneous seabed assumption may no longer be applicable. To reduce the response of a very large floating body, breakwaters are often set around the floating body. Due to the refraction

effect of the breakwater wall, the location of the very large floating body and the interaction between the breakwater and VLFS should be considered. In addition, due to the large size of the VLFS, which can span several kilometers of sea area, the sea conditions at both ends are very different; therefore, it cannot be described by a single spectrum. The displacement response and load of the structure may be increased under inhomogeneous sea conditions. There are two methods to predict the hydroelastic response under inhomogeneous sea conditions.

Three-Dimensional Hydroelastic Method

Based on the three-dimensional hydroelastic theory, Ding et al. (2019) developed a simplified method to estimate the hydroelastic response of the VLFS, which can consider the inhomogeneous incident wave angle. Compared with the experimental results, although there are some errors, the simplified model can to some extent predict the hydroelastic response of the VLFS. A schematic of the VLFS model and the comparison between the predictions and experimental results are shown in Figs. 5 and 6.

A Discrete Module-Based Hydroelastic Method

There is a new method to address fluid-structure coupling proposed by the Fu Shixiao group from Shanghai Jiaotong University (Wei et al. 2017,

Hydroelasticity Theory, Fig. 6 Significant values of motions of module 1 and 4 from the predictions and model tests (Ding et al. 2019)

Hydroelasticity Theory, Fig. 7 Flow diagram of the numerical simulation (Wei et al. 2017)

2018, 2019; Li et al. 2018). Figure 7 provides an overview of the process performing discrete module-based hydroelastic analysis. The floating structure is first discretized into a set of rigid

modules that are connected by elastic beams. Considering the hydrodynamic interactions between modules, multibody hydrodynamic theory is adopted to obtain the velocity potential of

the flow field and the wave excitation forces, added mass, and damping coefficients of various modules. The motions of each module are affected by the hydrodynamic interactions with the surrounding modules and are restricted by the displacement continuity of adjacent modules. The displacement continuity between modules is guaranteed by establishing an elastic beam with a uniform section stiffness matrix between the equivalent centers of the modules. The displacements can be obtained by solving the coupled kinetic equation. Then, the bending moments, shear forces, and torsional moments of the floating structure are determined based on the theory of structural mechanics.

Synonyms

Ice breaking ships; Icebreaker

Definition

Ice breaking vessel is also called icebreaker, a special purpose ship or boat designed to move and navigate through ice-covered waters and protect the ships entering and leaving the frozen ports and anchorages or guide the ships to navigate in the ice area. They are divided into river, lake, harbor, or sea ice breaking vessels.

Scientific Fundamentals

Characteristics of Ice Breaking Vessel

In the history of ship design and construction, icebreaker is a relatively late development ship. The earliest ice breaking ship in the world was born in Philadelphia, United States, in 1837, a ship named “City ice boat No. 1.” The first nuclear-powered icebreaker “Lenin” was born in the former Soviet Union in 1959. Ice breaking vessel shows obvious differences from normal ships in its strengthened hull, ice-clearing shape, and power (Hu 2004).

The hull of ice breaking vessel is short and wide, the ratio of length to width is small, the bottom ends are upturned, forward perpendicular is sharp and forward, and the overall strength is high. Stem, stern, and waterline areas are also strengthened with thick steel plates and dense skeletons. Additionally, the hull lines of icebreaker are usually designed to make the flare at the waterline small enough, so as to minimize the ice breaking force. In consequence, the characteristics of ice breaking ships are a sloping or rounded stem with sloping sides and a short parallel midship to enhance maneuverability in ice (Roles et al. 1969). However, poor hydrodynamic efficiency and seakeeping characteristics of the spoon-shaped bow and round hull make the icebreaker easy to be influenced by slamming

(Riska 2011). Thus, the hull of an icebreaker is often at a balance between minimum ice resistance, maneuverability in ice, low hydrodynamic resistance, and adequate open water characteristics (Segercrantz 1989). There is a kind of hull which is wider in bow than in the stern. They are called “reamers,” and they can increase the width of the ice channel; therefore, frictional resistance in the aft ship is reduced, and the ship’s maneuverability in ice is improved. Low-friction paint is often used to reduce friction protecting the ship’s hull from corrosion; besides, making use of an explosion-welded abrasion-resistant stainless steel ice belt can also achieve the purpose. Auxiliary systems are used to reduce friction by forming a lubricating layer between the hull and the ice, for example, powerful water deluges and air bubbling systems. Pumping water between tanks on both sides of the vessel makes continuous rolling to reduce friction and makes progress through the ice easier (Segercrantz 1989). Over the years, to further reduce the ice resistance and create an ice-free channel, experimental bow designs like a cylindrical bow and the flat Thyssen-Waas bow have been tried a lot (Zhang et al. 2017).

Additional structural strengthening is required for icebreakers and other ships which are operating in ice-filled waters because of the existence of various global and local loads resulting from the contact between the hull of the vessel and the surrounding ice. Because ice pressures vary between different regions of the hull, for an ice-going vessel, the most strengthened areas are the bow which experiences the highest ice loads, and around the waterline, the additional reinforcement above and below the waterline forms a continuous ice belt around the ship (Guard 2012).

Short and stubby icebreakers are usually built with transverse framing, in which the shell plating is stiffened and the frames are placed about 400 to 1000 mm, relative to the longitudinal frame used in longer ships. Near the waterline, the frames running in vertical direction distribute the local ice loads on the shell plating to longitudinal girders called stringers, and they are supported by web frames and bulkheads that carry the global hull loads. In older ice-going vessel, the shell plating directly in contact with the ice can reach

50 mm thickness, and the high strength steel is used in the modern ice breaking vessel (Guard 2012). The yield strength is up to 500 MPa. The result is that with the same structural strength, the material thickness is smaller, and the steel weight is lower. Whatever the strength, the steel used in the hull structure of an ice breaking ship must be able to resist brittle fracture in low ambient temperatures and high loading conditions, both of which are typical phenomena in the waters covered with ice (Guard 2012; Norden 1989). From the development of power system, the propulsion capacity of icebreaker has improved significantly from steam power and diesel power to nuclear power. Since steam power has been unable to meet the needs of the current polar strategy, most of the power systems of ice breaking ships in the world have adopted the diesel power system, and more advanced is the nuclear propulsion system. From the propulsion device, both the steam engine and the diesel engine pass the power to the fixed pitch propeller through the deceleration gear. This kind of system is easily damaged by the mechanical damage caused by the propeller hitting the broken ice produced with ice breaking process. At present, most ice breaking vessels have improved to use of electric drive, separating the original motive from the propeller to reduce the damage of ice impact, making the engine room more flexible, and no longer needing the drive shaft and the deceleration gear. At the same time, a nozzle or diversion pipe is added around the propeller, which not only better protects the propeller but also improves hydrodynamic factors around the propeller and increases thrusting power. In addition, the most advanced icebreaker also uses an omnidirectional pod system, a closed device suspended under the hull of a ship, which contains an electric motor directly connected with the propeller. The omnidirectional pod can be rotated at 360°, thus forcing propulsion in any direction. This podded thruster cooperates with the lateral propeller of the bow. It can realize the dynamic positioning of the ship and greatly improve the mobility of the icebreaker in the ice and open waters (Shen and Zhao 2010).

The main features of ice breaking vessel above can be summarized as follows:

1. Compared with hull size, icebreaker has greater weight and can crush sea ice more effectively.
2. The hull under the waterline uses special coatings to reduce the friction between hull and ice at low temperatures.
3. Special steel which has high performance at low temperature is used for extra thickening near the bow, stern, and water line;
4. Have a gentler angle of the bow, making icebreaker more accessible to climb up ice.
5. No anti-roll device and hull outburst.
6. High-power thrusters.
7. The shape of the hull helps protect the rudder and propeller. It prevents the rudder and propeller from being damaged by sea ice when reversing.

Ice Breaking Mode

Ice breaking capability is one of the most important parameters of ice breaking ships, which can be divided into continuous ice breaking capacity and repeated punching ice breaking capacity (Guard 2012). At present, most of the diesel icebreaker has a continuous ice breaking capacity of more than 1.2 m, and more advanced ice-going vessel can break 1.8 m, and nuclear power system ice breaking ships can break the ice of 2–3 m thickness continuously (e.g., Russian “Tamil” continuous voyage in level ice with thickness of 2 m; a more powerful icebreaker “Victory 50th anniversary” can break the ice with thickness of 3 m) (Yu et al. 2017).

In addition to using their own weight, the traditional ice breaking vessel usually needs to coordinate the front and rear pressure tanks to complete the ice breaking operation. For example, when the heading is breaking ice, the back-pressure tank is filled with water, so that the bow is upwards and keeps going, the front half of the hull is pressed on the ice, then the front-pressure tank is filled with water, and the back-pressure tank is drained, and the ice is crushed as the hull center of gravity moves forward; when both the left and right sides are breaking ice, the ballast tanks at left and right are injected water alternately, so that the hull is swaying, thus breaking the ice. However, when ice breaking vessel is

difficult to navigate continuously in ice regions, it can carry out the ice breaking operation by repeated stamping. First, the icebreaker needs to reverse the distance of the 1–2 length of ship, and accelerate forward, then the ice will be broken. The bow of the icebreaker is able to flush the ice easily, with the weight of the hull and the ballast water, so that the ice can be broken into pieces. In thicker ice areas or ice ridges, icebreaker breaks ice through repeated collisions several times.

Generally speaking, the ice breaking thickness of an icebreaker in repeated punching mode is usually two to four times of the breaking ice thickness using continuous mode. For example, Russian “Arctic” can break ice continuously with thickness of 2.25 m, and repeated punching can break ice with 5 m thickness; with American “Polar Star,” the thickness of continuous ice breaking is 1.8 m at the speed of 3 kn, and the thickness of repeated stamping ice breaking can reach 6.4 m.

In addition, it is common to use auxiliary ice breaking equipment/systems including flushing system, bubble system, hull heating equipment, and rapid rollover system. For example, the largest nuclear-powered icebreaker “Arctic” is installed with the tile system and the rapid tilting system. The bubble system can eject highly compressed air from the bottom of the hull, making the ice block on the side of the ship acting on the upward buoyancy and breaking up with the rise of the bubble to reduce the friction of the hull; the rapid lateral inclination system of the ship can change the weight distribution of the hull through a powerful pumping system, so that the hull will be swayed under the ice in tight condition, and the ship body can be shackled away from the ice and snow on both sides. In addition, Russian “Vladislav•Sterinov” icebreaker is installed with the hull heating equipment, which can be heated to prevent the hull from freezing, thus avoiding the toughness of the hull steel due to low temperature.

Special Ice Breaking Vessel

Asymmetric Professional Ice Breaking Ship

Due to special functional requirements and power requirements, the size of professional icebreaker

cannot be too large, especially for the limitation of ship width (usually around 20 m). With the increasing demand for transportation and the development of harbor waterway, the 20 m ship wide icebreaker has been unable to meet the growing actual demand. The traditional method is to break the ice using two ice breaking vessels at the same time, but this greatly improves the cost of breaking the ice. To solve this problem, ship design experts have developed and designed a new type of asymmetric hull ice breaking ship “Baltika,” which is 76.4 m in length and 20.5 m in width and has a draught of 6.3 m in summer. The ship can sail diagonally. When the thickness of ice is 60 cm, a channel with width of 50 m can be opened at 2 kn. The average hull width of the icebreaker in the Baltic Sea is 25 m, and the width of an Apollo type tanker is more than 40 m, so with the help of “Baltika” icebreaker, it can replace two ordinary icebreakers. In addition, it is more efficient to navigate at a speed of 3 kn in ice with 1 m thickness and navigate at a speed of 6 kn in ice of 60 cm thickness, and the maximum speed in open water is 14 kn. With the integration of this unique ship type and full rotary propulsion technology, this icebreaker also has good flexibility, versatility, and maneuverability.

Bi-Directional Ice Breaking Vessel

Bi-directional ice breaking vessel, or called double acting ice breaking vessel, is a new type of ice breaking vessel that supplements and strengthens ice breaking functions on the basis of dual power technology, such as the first double-powered icebreaker “Vasily Dinkov.” The stem and stern direction of the bi-directional icebreaker can carry out continuous ice breaking operation. It is suitable for navigation in open waters when the bow is forward, and it can be suitable for ice breaking operation when the ship stern goes forward, so as to balance the combination properties both in ice breaking and open waters. It is important to note that the operation of a bi-directional icebreaker at the stern of the icebreaker does not simply strike the ice, but flexibly turns the full rotary thruster back and forth, using powerful water to flush, move, and crush the sea ice, so that it eventually collapses and reaches the

purpose of breaking the ice (especially ice ridge ice), and turning the stern of the ship as well as widen the channel. However, this process is slow relatively.

Ice Breaking Hovercraft

Hovercraft is also used to break ice. There are two different models for air cushion ice breaking mechanism: low speed mode and high speed mode (Buck and Pritchett 1978; Muller 1979).

In low speed operating mode, the air cushion pressure causes the surface of the ice to fall down. The simplified model of the ice is a cantilever beam model without the support of water, so the ice is broken when the stress of the ice is large enough.

In high speed mode, ice breaking occurs when the velocity of energy transmission in ice is equal to the velocity of the air cushion icebreaker. The energy of the ice cannot be radiated and accumulates continuously, so that the amplitude of the fluctuation of the ice is increasing, and the tensile stress in the ice exceeds the yield limit of the ice. Therefore, the key to ice breaking at high speed is to find the speed of ice-water energy transmission, that is, critical speed. Besides, air cushion icebreaker parameters such as air cushion pressure and air cushion height also affect the ice breaking process.

Synonyms

Ice management system; Iceberg management; Physical ice management; Sea ice management

Definition

Ice management (IM) is defined in ISO 35104 as the sum of all activities, carried out with the objective to mitigate hazardous situations by reducing or avoiding actions from any kind of ice (sea ice or glacial ice). This includes, but is not limited to:

1. Ice detection, including tracking and forecasting

2. Threat evaluation, including procedures to identify potentially hazardous ice features or ice situations
3. Physical ice management, including methods to physically manage hazardous ice features or ice situations (e.g., icebreaking, ice clearing, iceberg towing)
4. Ice alert procedures designed to initiate appropriate operational reactions to ice hazards or adverse ice situations in a timely manner
5. Procedures associated with the safe shutdown of floating structures (moored or dynamic positioning), both active (move off and ice management) and semi passive (ice management, but no move off)
6. Procedures associated with the safe shutdown of bottom-founded structures, both active (with ice management and move-off capability) and passive (fixed with ice management)

Typical components of an ice management system are illustrated in Fig. 1.

Scientific Fundamentals

Ice management involves various operational procedures that can be used to reduce global and local design ice actions. General requirements of an ice management system and recommendations and guidance for the design of Arctic offshore structures can be found in ISO 19906. There is also a plenty of literature on ice management and associated systems. Some highlights of the relevant methods and techniques are presented below.

Ice Detection

Typically, surface scouting tools such as satellites, fixed wing aircrafts, helicopters, marine radars, drift buoys, and visual observations from icebreakers have been used for ice detection. By studying previous experiences with ice management, Eik (2008) stated that no single tool or method was able to detect all kind of ice features. Use of unmanned aerial vehicle (UAV), autonomous underwater vehicle (AUV), and multibeam sonar may be considered as possible future supplements to existing ice detection tools (Eik and

Ice Management in Offshore Operations,

Fig. 1 Typical components of an ice management system. (Figure based on ISO 19906)

Løset 2009). There is also a need to develop tools for gathering, analyzing, and presenting all information in a quick and efficient manner.

Threat Evaluation

According to ISO 19906, the methods used for threat evaluation should consider the information provided by the ice detection system; forecast movements and changes to any ice threats and their expected time of arrival; characterize ice events in terms of potential consequences to the installation for the various operations and phases of the development; identify circumstances when active intervention in the form of physical ice management activities is required; and identify the thresholds where installation-specific operational response actions (e.g., production shut-down, disconnect, personnel evacuation) are triggered and the advance warning time required for the response actions to be carried out.

Ice Alert Procedures

Ice alert procedures provide an indication of the severity of ice conditions affecting an offshore operation, identify hazardous ice features or situations to it, and outline a series of pre-defined response actions, including physical ice management. An effective ice alert procedure is critical to

operations and is designed to ensure that personnel on the installation, its support vessels, and the management ashore understand the ice situation, so they can immediately recognize and address changing circumstances. A typical ice alert system uses a color (or number) code to indicate the level of threat. To ensure that appropriate actions are taken by the installation and its support vessels in various ice conditions, alert levels can be defined by the proximity of potentially hazardous ice conditions to the operations area and/or the observed responses of the installation (Dunderdale and Wright 2005).

Physical Ice Management

Physical ice management refers to the actual vessel operations that are intended to break up and clear sea ice and/or specific features within an ice cover and deflect icebergs and small glacial ice masses (ISO 19906). Specific approaches and techniques have been developed for both sea ice and iceberg management.

Sea Ice Management

Dunderdale and Wright (2005) described five basic sea ice management techniques used to reduce ice load levels and defend floating platforms that are station-keeping on a mooring or by

dynamic positioning. Three of the five basic techniques involve particular icebreaking patterns, including the linear, sector, and circular techniques. The remaining two are ice clearing procedures that include pushing heavy ice floes and the use of high-power propeller wash to break thin ice and clear brash ice and small floes from around the station-keeping unit.

1. **Linear technique:** The linear technique is an icebreaking pattern used by a support vessel to break pack ice up-drift of a floating platform in straight lines, parallel to the direction of ice drift. This icebreaking pattern is typically used when the ice drift speed is fast and the ice drift direction remains reasonably constant.
2. **Sector technique:** The sector technique is an icebreaking pattern that provides wide managed pack ice coverage around the approaching ice drift direction. This technique requires the support vessel to steam back and forth across the drift line between two designated bearings that create the sector. This pattern is typically used when ice drift speed is slow and/or when the drift direction is variable or changing rapidly.
3. **Circular technique:** The circular icebreaking technique is a procedure that requires the support vessel to steam in a circular pattern up-drift of the platform location. The diameter of the circles will vary with the speed of the ice drift and the maneuverability and speed of the support vessel. This pattern is typically used in high concentrations of thin ice or small diameter thick ice floes and when the ice drift direction is variable. A circular pattern is also made completely around a platform as an effective method to relieve ice pressure.
4. **Ice pushing technique:** The ice pushing technique is an effective way of removing medium and large ice floes from the drift line. The pushing direction is usually at right angles to the approaching ice. The benefit of pushing a large floe instead of breaking it is that the threat to the platform is removed from the drift line, whereas if the ice is broken up-drift, the broken remnants may still pose a threat. Care must be taken to properly forecast any change to the ice

drift to ensure that the ice will not become a threat at a later time. To allow full power pushing, the bow strength of the vessel used must be appropriate. At least two vessels are often used to prevent floe rotations.

5. **Propeller washing technique:** Propeller washing of small pieces of thick ice, even if present in high concentrations, can be very effective to reduce or prevent ice accumulation against the platform. This technique is particularly effective when used by vessels fitted with azimuth thrusters. Such a system allows the support vessel to remain almost stationary up-drift of the platform on the drift line, with the propellers angled outward and using high power to wash ice to each side of the platform. There are sometimes restrictions to the use of this approach, for example, if there is only one vessel and poor visibility which prevents knowing what ice may be coming from further up drift.

In addition to these techniques, there are a number of variations and combinations that are effective in certain ice situations. When more than one ice management vessel is operating up-drift of an installation, each can use a different technique that is most suitable for its operating capability.

Iceberg Management

McClintock et al. (2007) summarized the iceberg towing and deflection techniques used on the Grand Banks.

1. **Single vessel iceberg towing procedure:** The standard method for deflecting an iceberg posing a threat to offshore facilities has been to encircle the iceberg with a heavy floating rope which can act as a bridle from which the iceberg may be towed by an offshore supply vessel. For larger icebergs, the objective is to deflect the ice mass by a few degrees from its naturally preferred route. The technique has good reliability for medium to large icebergs but is ineffective for small iceberg.
2. **Dual vessel towing:** Towing is conducted with two vessels to deflect large or unstable ice masses. The approach requires two vessels, a

single wire rope, and one steel hawser for each vessel. The approach is practical and can produce a significantly greater tow force; however, there can be difficulties in having a balanced vessel thrust, a tendency to see-saw around the iceberg while towing, and difficulty in maintaining depth control over the tow wire.

3. **Water Cannon:** Water cannons are actually fire monitors or nozzles mounted on the superstructure of the support vessels which can direct a high-pressure stream of sea water to deflect small ice masses. While their primary function is firefighting, tests and experience have proven them highly effective in managing small ice masses which might not be towable.
4. **Propeller washing:** Propeller washing can be a generally successful technique for small ice mass deflection, typically used when a bergy bit or growler is close to facilities and its drift path can be accurately predicted. The tow vessel repeatedly backs up to the piece of ice and accelerates away, thus moving the ice in the desired direction with the backward thrust of the water from the propellers.

Station-Keeping Considerations

There are a wide range of platforms and vessels that have been used in almost any kind of ice regime (Eik 2008). Some representative systems and associated station-keeping techniques were viewed by Dunderdale and Wright (2005).

1. **Gravity-based platforms** (e.g., the Hibernia GBS) are typically designed with the ability to withstand the loads from large iceberg impacts and hence have an inherent capacity to withstand pack ice interactions. As a result, ice management is not required to support them, from the standpoint of keeping ice load levels within acceptable levels. However, ice management will, at times, be required to support some of the operations that may be carried out around a GBS platform. For example, ice management would be needed for the safe operation of tanker loading system.
2. **Turret moored FPSOs, DP vessels, and tankers** that are moored at single point loading facilities have a distinct advantage over floating systems anchored with fixed alignments, since they can vane into moving pack ice, thereby presenting a much reduced profile to any ice interactions. In most cases, ice management support will be needed to keep load levels and any other adverse ice effects on these vessels within acceptable levels, at least in heavy pack ice conditions. While station-keeping, vessels fitted with multiple thrusters can use strategically directed propulsion wash to help reduce ice accumulations and some ice impacts and enhance the smooth flow of ice and its clearance around them. These types of capabilities and maneuvers would help to reduce the amount of pack ice that needs to be managed up-drift by support vessels. Also, turret moored and dynamically positioned vessels can move off a location on very short notice, once their production or loading operations have been suspended. However, a turret moored FPSO may require considerable time to reconnect to a released mooring system. Ice capable support vessels can also play a role in escorting such vessels through ice and in helping them reconnect.
3. **Semi-submersible rigs and drillships** are typically anchored with either 8 or 12 anchor lines. They are generally used to drill exploration and production wells and are not “permanent” platforms like a GBS or FPSO. When these types of structures are used for operations in ice, consideration would have to be given to the effectiveness of ice management support in reducing the global ice actions. Ice management would also be required to prevent local ice loads on their hulls, which are often only nominally ice strengthened. Another consideration of particular importance for the operation of a semi-submersible in pack ice is the effect of any ice interaction with the risers which, on most rigs, are not enclosed within a leg but are exposed. If pack ice conditions become threatening and a decision made for a semi-submersible or drillship to vacate location, consideration must be given to the possibility that anchor systems will need to be retrieved in the existing pack ice conditions. In some circumstances, ice management may be required by each of the anchor

handling vessels during the recovery and return of anchor systems to the rig. As a contingency, all moorings used by anchored vessels operating in ice are fitted with some type of emergency quick release system. Various methods are used to disconnect mooring chains from the rig such as a chain “shear link” or an acoustic release mechanism between the mooring wire and anchor. Issues associated with a “quick rig release” include careful positioning of the mooring where the ends to be dropped stay clear of any sub-sea assets and the considerable amount of time and work necessary to retrieve and restore anchor systems back onto the rig. Once a rig moves off location and is underway, additional consideration must be given to towage. In this regard, ice escort may be necessary to move the rig from the location to open water.

Evaluation of Ice Management Capabilities

1. **Evaluation of sea ice management:** Eik (2011) presented a method for including sea ice management in a structural reliability analysis. The approach focused on how icebreakers or offshore installation disconnection capabilities might alter ice load distributions and thereby reduce the probability of failure. To demonstrate the approach, a moored symmetrical structure (i.e., “Kulluk-type”) in the central Barents Sea was considered. Realistic ice data from a probabilistic ice drift simulator was used as a basis, and ice loads were calculated for a 1000-year period. The load calculations were based on the transformation of all developing ice conditions into a standardized equivalent ice thickness. Empirical formulations for ice resistance on icebreaking vessels were combined with “max-to-mean ratios” from physical tank-model tests to estimate peak loads. The demonstration revealed a need for more relevant ice load models that are valid both for managed and unmanaged ice. In a severe ice environment, it was found that the icebreaker’s ability to reduce ice loads was insufficient to reduce the most extreme loads. The ability to disconnect moorings and risers and escape the site prior to abnormal ice events would ensure that the ice loads were within an acceptable range, conditional that the disconnection capabilities were sufficiently reliable. A fault-tree analysis including failure probabilities in ice management operations and/or disconnection operations was considered useful for estimating the frequency of specified accidents.
2. **Evaluation of iceberg management:** A method for the systematic evaluation of an iceberg management system and its impact on the design of offshore structures was also introduced by Eik and Gudmestad (2010). The approach was based on the combination of a numerical iceberg drift model and a probabilistic analysis with the event tree model. Experiences from the Canadian iceberg detection studies and iceberg deflection operations were also incorporated into the model. For a selected site in the Barents Sea, it was found that the maximum impact load corresponding to a 10,000-year event was 85 MJ for a concept without any iceberg management capabilities. An alternative system with iceberg detection, iceberg deflection, and disconnection capabilities including emergency disconnect indicated a corresponding abnormal load of about 1.8 MJ.
3. **Evaluation of mooring load in managed ice:** Monitoring of ice conditions and measurements of ice forces have provided a comprehensive and unique set of data from the full-scale experience with the Kulluk structure (a conical drilling unit used in the Beaufort Sea). The monitoring included records of ice cover conditions as well as descriptions of ice management operations. The ice forces were measured using the tension values on the mooring lines. Wright (1999) carried out a comprehensive analysis of the observations and measurements, in which the ice loading episodes were summarized in a manner that clearly linked ice forces to ice conditions, ice management activities, and the mode of ice interaction with the structure. Su et al. (2019) carried out a numerical study of the Kulluk structure in managed ice as well as some “extreme events” reported by Wright (1999). The simulation shown in Fig. 2 refers to one of these “extreme events”: a 500 m diameter

Ice Management in Offshore Operations,

Fig. 2 Numerical simulation of an “extreme event” reported by Wright (1999)

Ice Management in Offshore Operations,

Fig. 3 Numerical simulation of the Kulluk structure in managed ice

and nearly 2.5-m-thick ice floe impacted the Kulluk structure (with a mooring stiffness of 350 t/m) at 0.3 m/s and produced a peak load of about 600 t (5.88 MN), before it rotated around (Wright 1999). The simulation shown in Fig. 3 refers to a managed ice condition (ice concentration, 90%; ice thickness, 2.5–2.7 m; floe size, 30–50 m; drift speed, 0.3 m/s). The simulated time series of ice and mooring loads are given in Figs. 4 and 5, respectively. These two simulated cases directly show that ice

management can contribute to a significant reduction of ice load level (from about 6 MN to 1 MN), which has also been concluded by assessing the full-scale data (Wright 1999).

Key Applications

Ice management is most commonly used to support floating systems in both sea ice and glacial ice environments and can significantly influence the

Ice Management in Offshore Operations,
Fig. 4 Simulated ice and mooring loads under the “extreme event”

Ice Management in Offshore Operations,
Fig. 5 Simulated ice and mooring loads in managed ice

design philosophy that is adopted for them. It can also be used to mitigate the risk of deep draught ice features interacting with sea floor facilities. In certain cases, ice management can be used as a means of modifying ice actions on fixed structures, although this approach is not common. It is also a relevant consideration in terms of supporting other in-ice activities, such as Evacuation, Escape and Rescue (EER) systems and tanker offloading operations.

The oil and gas industry have already been involved in different ice management activities for a long time (more than 40 years) and in several geographical areas (Eik 2008):

1. **Beaufort Sea:** Sophisticated ice management systems were developed for the exploratory drilling in the Beaufort Sea, where the conventional drillships (since the 1970s) and a
2. **East coast of Canada – Grand Banks:** The occurrence of drifting icebergs is the dominating threat for the petroleum production on the Grand Banks. During the years with

conical drilling unit – Kulluk (since the 1980s) – were used. During operations the Kulluk structure experienced thick first-year ice, large pressure ridges, heavy rubble, and high concentrations of drifting multi-year ice. The experiences with the Kulluk structure provide the best source of data for most considerations related to moored structure in various pack ice conditions with ice management activities (Wright 1999; Dunderdale and Wright 2005). In 2009, a comprehensive series of ice management trials were conducted in the Fram Strait to evaluate the performance of the icebreakers in mainly second-year ice (Maddock et al. 2011).

- activities on the Grand Banks, experiences from physical iceberg management operations (since the 1970s) have been collected, reported, and presented in a publicly available database (PERD Comprehensive Iceberg Management Database, Rudkin et al. 2005).
3. **West coast of Greenland – Fyllas Banke:** Over a period of 10 weeks in 2000, exploration drilling was carried out at a water depth of 1150 m offshore central west Greenland in the Fylla field. During the drilling, valuable information regarding icebergs as well as practical experience regarding iceberg management was gained (McClintock et al. 2002).
 4. **The Greenland Sea:** In order to evaluate and test various ice management technologies, full-scale trials offshore north-east Greenland were performed in 2012 and 2013 within the framework of the Oden Arctic Technology Research Cruise (OATRC) program (Scibilia et al. 2014).
 5. **The Arctic Ocean:** As a part of the International Ocean Drilling Program (IODP), a multiple vessel expedition was sent into the Arctic Ocean in 2004 to drill and recover deeply buried sediments at the Lomonosov Ridge. Two icebreakers worked up-drift of a drillship in a two-stage ice management configuration, and the drillship was able to remain on station for up to 9 days in 1100–1300 m water using manual dynamic positioning control (Moran et al. 2006). A research cruise (OATRC2015) was performed in the Arctic Ocean in 2015. One of the main objectives of this cruise was to collect full-scale data necessary to build, calibrate, and validate theoretical models for ice management operations (Lubbad et al. 2018).
 6. **Barents Sea:** During a data collection expedition in the northeastern part of the Barents Sea, an attempt to tow an iceberg frozen into sea ice was carried out (Eik 2008).
 7. **Pechora Sea:** In 2000, an offshore oil-loading facility was built at Varandey in the Pechora Sea. At least one icebreaker was used to break and clear the ice around a single loading hose.
 8. **Sakhalin:** In order to produce oil from the Piltun-Astokhskoye field (Sakhalin 2), the Vityaz Production Complex was developed, and ice management operations were required. With respect to new technology, it has been reported by Keinonen (2007) that the introduction of icebreaking support vessels, equipped with azimuth propeller systems, has significantly improved the ice management capabilities.
 9. **North Caspian Sea:** In addition to icebreaker support (Arpiainen et al. 1999), physical ice barriers (e.g., steel piles and caissons) have also been used as passive ice management protection during exploration drilling in the North Caspian Sea.
 10. **Bohai Sea:** In the Bohai Sea, which is a typical area of marginal oil field, most of the offshore oil and gas platforms are in a seasonally frozen region. Specific sea ice management systems have been established based on years of field monitoring and research (Zhang et al. 2017).

Definition

Ice tank test is used to investigate various ice–structure interactions in an ice tank under scaled conditions. An ***ice tank*** is a model basin whose purpose is to provide a physical modeling environment for the interaction of ship, structures, or sea floor with both ice and water.

General

Ice tank test can be used to investigate various ice–structure interactions and offers the advantage that relatively complex problems (that can be difficult to analyze using other methods) can be studied and visualized at a small scale (i.e., smaller than full scale). An ice tank is a model basin or tank whose purpose is to provide a physical modeling environment for the interaction of ship, structures, or sea floor with both ice and water. Ice tanks may take the form of either a towing tank or maneuvering basin.

Generally, ice model tests have been used to investigate global ice actions resulting from

moving ice, such as the expected ice actions and/or the expected ice interaction modes (e.g., ice failure modes, ice ride up, the buildup of ice rubble around a structure, ice clearing behavior around a structure, ice blockage, etc.). Ice tank test is a flexible tool that has been applied to many ice–structure interaction cases such as:

- (a) Various structure types; the types tested include:
 - Large vertical or multifaceted caissons (e.g., Cornett and Timco 1998)
 - Upward breaking and downward breaking cones (e.g., Huang 2010; see Fig. 1)
 - Narrow versus wide structures (e.g., Huang et al. 2017).
 - Multi-leg structures (e.g., Huang et al. 2013; Li et al. 2017; see Fig. 2)
 - Berms
 - Moored versus bottom-founded structures (e.g., Evers and Jochmann 2011; see Fig. 3)
 - Satellite structures placed near a drilling structure to provide ice protection, and access for EER craft or protection for quay areas
- (b) Various ice features interacting with a structure, such as:
 - Sheet ice
 - First-year ridges
 - Multi-year ridges
 - Broken ice, and floe ice conditions

Table 1 lists common ice processes treated by means of physical modeling and indicates the important variables influencing them. Model reliability depends on the accuracy with which the model replicates those variables. Note that some modeling situations can involve a combination of processes. Consequently, the variables can be grouped differently as shown in Table 1 (Zufelt and Ettema 1996).

Only a limited number of comparisons have been made between model scale and full-scale results for structures, although several correlation studies have been done for icebreaking ships (e.g., Wang and Jones 2008). Ice model tests have been conducted at different scales for fixed icebreaking conical structures. Comparisons are made for the Kulluk (a large downward breaking floating conical structure) between model tests conducted at different ice tanks and field data collected while it was on station in the Beaufort Sea (Comfort et al. 1999).

A problem of major concern in planning a model test program is the type of ice. Not all ice problems can be investigated reliably using present-day ice tank modeling techniques. An ice model test program should be targeted to investigate the specific ice interaction problem of interest. Sometimes, it is preferable to test a simplified, basic problem in the ice tank, and then use these results to assess an overall problem that is more complex.

Ice Tank Test, Fig. 1 Model ice failure in an ice-breaking cone test. (Huang 2010)

Ice Tank Test, Fig. 2 Model ice failure in front of a multi-leg structure. (Li et al. 2017)

Ice Tank Test, Fig. 3 Moored tanker in ice tank with underwater illustration. (Evers and Jochmann 2011)

Ice Tank Test, Table 1 Ice processes and variables that it is important to model

Ice process	Variables of importance
Ice sheet deflection	Ice flexural strength
	Modulus of elasticity
	Loading rate
	Ice thickness
Ice ridging	Velocity of parent ice sheet
	Ice thickness of parent ice sheet
	Ice–ice friction
	Ice sheet strength (flexural, crushing, and shear)
	Keel depth
	Sail height
	Consolidated layer
Ice–structure interaction	Structure stiffness
	Dynamic characteristics of structure/mooring system
	Velocity of ice sheet
	Ice thickness
	Ice sheet strength (crushing, flexural, and shear)
	Ice–ice and ice–structure friction
	Mode of breaking (crushing, flexure, and shear)
	Ridge properties and dimensions
Icebreaker modeling	Vessel speed
	Ice–ice and ice–hull friction
	Ice thickness
	Ice sheet strength (crushing, flexural, and shear)
	Ice piece size
	Piece movement around hull and propeller
	Mode of breaking (crushing, flexure, and shear)
	Ridge properties and dimensions

Previous investigations of ice ride up and ridge building are examples where this approach has been used. Initially, simple model tests were

done to investigate ice ride up and ridge building processes. These basic data are part of the information set that is used to address more complex issues such as

- Designing islands and structures to avoid ice ride up problems
- Quantifying pack ice driving actions and developing satellite structures designed to form protective rubble around drilling structures in the Beaufort Sea

Scaling uncertainties and modeling artifacts are another important issue that should be considered in planning an ice model test program (von Bock und Polach and Molyneux 2017). These can arise from imperfections in the ice modeling material being used. Some model ices are better able to simulate some types of ice interactions than others.

Scaling

When model testing is used for ice–structure interactions, appropriate scaling relationships should be selected to represent the mechanisms or processes that dominate the ice actions or response to ice actions. In the physical modeling of ice and structure interactions, Froude similarity (the ratio of inertial to gravitational load) and Cauchy similarity (the ratio of inertial to elastic forces) are maintained between the prototype and the model (Timco 1984). Considerable effort has been expended on the development of model ice with mechanical properties scaled to prototype ice and

with analogous failure behavior. There can also be rigorous modeling of the structure shape, stiffness, and surface characteristics. As long as the failure modes expected in the prototype are correctly simulated, model tests can provide an important input into the design process. Model ice can provide optimum simulation of ice interactions only over a certain range of scale factors, generally within about 10 to 50. Tests done at scale factors that are too high are likely to produce results that are subject to modeling distortions.

Scaling is accomplished by observing the Froude scaling law, as given in Eq. (1), and the Cauchy scaling law, as given in Eq. (2):

$$Fr = V / \sqrt{gL} \quad (1)$$

$$Ca = \rho_w V^2 / E \quad (2)$$

where:

Fr is the Froude number, the ratio of inertial to gravitational forces.

Ca is the Cauchy number, the ratio of inertial to elastic forces

V is the speed, expressed in meters per second

g is the acceleration of gravity, expressed in meters per second squared

L is the length dimension, expressed in meters

ρ_w is the density of water, expressed in kilograms per cubic meter

E is the modulus of elasticity of ice (Young's modulus), expressed in megapascals

Since inertial and gravitational forces dominate free-surface flow, the Froude number is generally used as the similitude criterion for ice basin modeling. The Cauchy number, then, provides the necessary scaling for material parameters. It is not possible in model tests to simultaneously satisfy the requirements of Reynolds law, which governs viscous effects, with those of Froude/Cauchy scaling. Since viscous effects are relatively small for ice model tests at low speeds, Reynolds law is usually ignored.

In order to satisfy the Froude and Cauchy laws, the various geometrical and physical quantities of the tested objects should be scaled according to Table 2.

Ice Tank Test, Table 2 Scale relations

Physical values	Model scale	Full scale
Ice thickness	h'	$h = \lambda h'$
Flexural strength of ice	σ_f'	$\sigma_f = \lambda \sigma_f'$
Elastic modulus of ice	E'	$E = \lambda E'$
Density of water	ρ_w'	$\rho_w = \rho_w'$
Density of ice	ρ_i'	$\rho_i = \rho_i'$
Time	t'	$t = \lambda^{1/2} t'$
Velocity	V'	$V = \lambda^{1/2} V'$
Force	F'	$F = \lambda^3 F'$
Friction coefficient	μ'	$\mu = \mu'$

NOTE: λ is the geometric scale factor

Test Methods

Model Ice Types

Natural sea ice behaves as a brittle or ductile material depending primarily on its temperature, salinity, and strain rate. Basic mechanical properties of the natural ice, such as strength and deformation, also depend mainly on the strain rate, ice temperature, and salinity content in the ice. Flexural strength is conventionally considered independent from strain rate (Timco and Weeks 2010). Ideally, model ice should behave in the same manner when applying Froude scaling law, i.e., the strengths should be related by a linear scale factor, λ .

In the past decades, significant effort was made in finding the ideal material for model ice. Different approaches used to produce model ice include synthetic ice, hybrid ice, and refrigerated ice. Currently, refrigerated ice is the most widely used model ice. To scale the ice properties correctly, the ice is doped by sodium chloride or other chemical dopants, such as ethylene glycol and detergent. A wet seeding technique can be used to produce a fine, crystalline, columnar structured ice (see, e.g., Fig. 4). A fine-grained ice can be produced by spraying a saline solution during the entire ice growth process, resulting in a granular structured ice similar to snow ice (see, e.g., Fig. 5). Further model ice development includes the injection into the water of air bubbles that are entrained into the growing ice crystals to increase brittleness and decrease ice density.

Ice Tank Test, Fig. 4 Columnar structured model ice. (Sun and Huang 2020)

Ice Tank Test, Fig. 5 Granular structured model ice. (von bock und Polach 2016)

It is important to note that a standard “model ice” has not yet been established, and judgment is required to ensure that the model ice used is appropriate for the ice–structure interaction of interest, in combination with other factors such as the size and capabilities of the ice tank.

Testing Technique

In general, two testing options are used in ice model tanks. The first method is to push or pull the model through a stationary ice sheet; the second is to have a moving ice sheet pushed against a fixed or moored model. The selected option should be consistent with the test

objectives. Parameters measured and the configuration of the measurement systems should be primarily dictated by the test objectives and the characteristics of the structure and its operational conditions.

Differences in the dimensions and layout of the ice tank facility can have some influence on the tests. An important factor is the effect of the basin size (length and width) on the number of tests that can be carried out with one ice sheet. The required actual test length depends on the type of test. As an example, for ice rubble formation tests or ice pileup tests, the model should be able to proceed until a steady state is reached. The other factor that can restrict the test program is the proximity of the basin walls. For the case when a model is pulled through ice, the level ice sheet can be considered to have infinite extent if the shortest distance from the point of application of any loads to the nearest tank wall is more than three times the characteristic length of the ice sheet (ITTC 2017).

The choice of testing technique depends strongly on the type of test. In particular, it should be appreciated that when pushing the ice sheet against a model of a fixed or moored structure, unrealistic cracks can often propagate from the model towards the sidewalls of the tank. In addition, the ice sheet can fail along the pushing plate instead of on the model; this happens especially for thin and brittle ice. As well as for the testing technique option, the most practical way to minimize negative consequences of the boundary condition deviation is to conduct tests with an ice sheet sufficiently wide relative to the model width.

Ice Conditions

Model tests can be performed in ice conditions such as level ice, rafted ice, a newly broken channel, brash ice (old channel), broken ice, rubble ice fields, and ridges. The proper documentation of the tests should include the method by which the ice conditions are simulated. It is recommended to document the ice conditions prior to and after the test by still photographs and video records, preferably from some elevation. The number, time, and location of ice thickness and property measurements should also be documented. Visible cracks in the ice extending from the broken

channel towards the basin walls or towards open water areas should be included in the report.

The thickness of the model ice should be measured after each level ice test and the number of measurements should be sufficient to adequately evaluate variations in ice thickness along the track of the model through the ice. In cases where test runs are performed close to the sidewalls of the ice tank, measurements should be taken on both sides of the broken channel.

In an old channel or rubble field, the thickness should be measured along two or more lines within the model track. Underwater sonar for scanning the lower surface of model ice and laser profiles for evaluation of ice upper surface or similar remote sensing devices is particularly advantageous for tests with ice rubbles/ridges or brash ice. Such measuring systems allow for the nondestructive acquisition of the ice thickness profiles or a 3D picture before running the test.

Ice ridges and rubble can contribute, in many cases, to the design actions on a structure, and conducting model tests for such conditions is of particular importance. Producing model ridges and rubble in compliance with the requirements of similitude theory is one of the most challenging tasks in ice–structure interaction modeling. The conventional method of creating a first-year ice ridge/rubble is to grow level ice with a thickness equal to the thickness of ice blocks constituting a model ridge/rubble, break this ice sheet into irregular pieces, and then collect these pieces into a pile. The resulting pile of ice is normally left exposed for some period of time to negative ambient air temperature in order to create a consolidated layer of the ridge/rubble.

In the course of ice ridge/rubble modeling, particular attention should be paid to modeling the effects of the interaction within the nonconsolidated part of the ice feature and to the mechanical properties of its refrozen part. The mechanical properties of the consolidated layer can be evaluated in the same way as for level ice, assuming that both sail and keel are carefully removed. For the measurements of the mechanical

properties of the nonconsolidated part, pull-up, punch, and/or shear tests can be employed.

Model Ice Properties

General

Different model testing facilities use different types of model ice materials. None of the existing model ice materials is absolutely perfect. Thus, ice properties measured for one type of material cannot be directly compared with another material. The geometrical parameters and mechanical properties of the model ice should be determined accurately, regardless of the material composition.

To maintain reliable results, it is recommended to perform property measurements in situ in the tank and, whenever possible, without lifting the samples out of the natural environment. The timing and location of the measurements are important. The measurements should be done as close as possible to the actual test area and test time. All measurement procedures should be as simple as possible and measure the desired parameter directly. The test procedures and measurements should be performed by qualified personnel and should be clearly documented. The equipment used in all measurements should be calibrated at the ambient temperatures of the ice tank.

Properties of first-year and multi-year ridges are very difficult to control in ice basins. Samples should be taken from parts of the ridge to document both consolidation and other internal properties. The ice conditions adjacent to the ridge should be documented. For instance, broken level ice surrounding a ridge reduces the actions substantially compared to intact level ice.

Flexural Strength and Modulus of Elasticity

The flexural strength and the modulus of elasticity are frequently determined by cantilever beam tests. A floating cantilever beam having length L and width B is cut in situ. The recommended dimensions of a beam ($L \times B \times h$) are $6h \times 2h \times h$, where h is the ice thickness. The tip of the beam is

loaded at a constant speed until the beam fails. It is recommended to use an electrically driven loading device. The applied load as well as the deflection of the beam should be recorded. The determination of the deflection is required only for the determination of the elastic modulus. Strength measurements should be carried out several times during the tempering phase and once after the ice test has been performed. Whenever possible, the strength should be measured at different locations distributed over the tank length. The flexural strength and the modulus of elasticity in bending can be calculated from the failure load and the free-end deflection measurements as given in Eq. (3) and (4), all in consistent SI units:

$$\sigma_f = \frac{6F_b L}{Bh^2} \quad (3)$$

$$E_f = \frac{4FL^3}{Bh^3\Delta} \quad (4)$$

where:

σ_f is the flexural strength in bending

E_f is the elastic modulus in bending

F is the load applied to the cantilever free end

F_b is the failure load

L is the length of the beam (load point to support)

B is the width of the beam (at the support)

h is the thickness of the ice

Δ is the deflection of the beam (cantilever free end)

An alternative method to measure the modulus of elasticity in bending is to measure the deflection of an infinite floating ice sheet under a given load. In this case, the elastic modulus is defined as given in Eq. (5):

$$E_f = \frac{3(1 - \nu^2)}{16\rho_w g h^3} \left(\frac{F}{\Delta}\right)^2 \quad (5)$$

where

ν is the Poisson ratio for ice

ρ_w is water density

g is acceleration due to gravity

Other designations are as for Eq. (4).

Compressive Ice Strength

The compressive strength of model ice can be measured using any of the following three methods:

- Uniaxial test is performed in the water
- Ice block is cut and lifted from the water to perform a uniaxial test
- Indenter is used to load the ice sheet horizontally

The compressive strength is the most difficult to measure with high accuracy and the structure of the model ice does not always allow the use of all of the above methods.

Friction Coefficient

The dynamic friction coefficient is determined through measurements of the tangential action when either a piece of model ice is slid along a plate, painted identically to the model structure, or such a plate slides over a piece of model ice. In both cases, the ice and the plate should be pressed together by a given normal action. The friction between two ice pieces can be determined using the same testing arrangements. The contact surfaces of the ice and the plate should be moistened, since wet and dry friction coefficients differ significantly. The friction tests should be performed at a speed corresponding to the ice–structure interaction velocity expected in the tests. The friction coefficient, μ , is calculated according to Coulomb's friction law as given in Eq. (6):

$$\mu = F_T / F_N \quad (6)$$

where

F_T is the mean measured tangential (friction) load during steady motion

F_N is the normal load on the contact surface

List of Ice Tanks (Table 3)

Ice Tank Test, Table 3 List of ice tanks

Ice tank facility	Location	Dimensions	Grain structure	Chemical composition

Definition

Iceberg scouring (also called *iceberg gouging*) is a phenomenon in which the bottom of an iceberg interacts with the seabed. It happens normally in shallow water areas due to the limited depth of icebergs. The drifting force of iceberg is the main driving factor in such interaction. If there are subsea pipelines or other structures installed in the same area, the *iceberg scouring* may present a potential hazard to the integrity of the subsea pipelines or structures. **Burry depth (BD)** is used to describe how deep a pipeline shall be buried against the iceberg scouring loads. To trench the seabed and burry the pipeline to a certain depth (*so-called burry depth*) is one way to lower the risk, but it significantly increases the project cost.

Scientific Fundamentals

Iceberg Drifting

Icebergs originated from the source glaciers are drifting on the sea surface under the combination of wind, gravity, wave, and current. The largest source of iceberg is the glacier located at Greenland (Denmark), see Fig. 1.

Iceberg Scouring, Fig. 1 Iceberg falling off from Greenland (Denmark) and Svalbard (Norway), drifting to shipping lanes and oil and gas fields in North Atlantic/Barents Sea (for illustration only)

The basic equation for the horizontal motion of an iceberg is as following (Bigg et al. 1997):

$$M \frac{d\mathbf{V}}{dt} = -Mf\mathbf{k} \times \mathbf{V} + \mathbf{F}_a + \mathbf{F}_w + \mathbf{F}_r + \mathbf{F}_s + \mathbf{F}_p \quad (1)$$

where M is the iceberg mass, $\mathbf{V}$ is the iceberg velocity, f is the Coriolis parameter, $\mathbf{k}$ is the unit vector directed vertical upwards, $\mathbf{F}_a$ is the air form drag, $\mathbf{F}_w$ is the water drag, $\mathbf{F}_r$ is the wave radiation force, $\mathbf{F}_s$ is the sea-ice drag (where applicable), and $\mathbf{F}_p$ is the horizontal pressure gradient force exerted by the water on the volume that the iceberg displaces. Besides the horizontal motion, the iceberg has potential off-horizontal plane rotation. The most stable iceberg is tabular and blocky iceberg. The domed, wedged, and pinnacled iceberg is not stable. They may roll completely over in seconds without any apparent reason; see Fig. 2 for a drifting pinnacled iceberg.

In the meanwhile, iceberg's mass and shape will be changed due to its melting and thus influence the drifting model. Løset (1993) presented a detailed numerical model simulating the iceberg melting. A rough estimation might be good

enough to be included in the drifting model considering the large amount of iceberg numbers and the long simulation time.

Iceberg Scouring

As shown in Fig. 3, the bottom of iceberg may have the chance to get contact with the seabed. The contact/interaction will continue until the balance of the driving force and the resistance from seabed soil. The scouring depth can reach 4 m or more. According to Palmer and Croasdale (2013), the iceberg scouring force is much higher than the anchor impact (approx. 1 MN or more). It could be imagined that if the pipeline is subjected iceberg scouring, significant damage might be obtained. Thus, it is a challenge to design a pipeline system in which the iceberg scouring is a potential threat. To rock dump or to trench the pipeline are two alternatives; however, both of them are not economical optimized solutions, especially considering the difficulties on predicting the necessary rock dump height or trench depth.

As shown in Fig. 1, the main potential iceberg risk areas are located at the eastern edge of the Grand Banks of Newfoundland (also called iceberg valley, the iceberg sank Titanic in 1912 came

from here) and the Barents Sea in Arctic (North to Norway). The offshore subsea facilities located on the iceberg drifting routes are subjected to the iceberg scouring problem. An example of this is shown in Fig. 4, which is from the seabed survey results of Snøhvit gas field. It lies in the Barents Sea, about 140 km northwest of Hammerfest in northern Norway. The fields were discovered in 1984 in 250–345 m of water and extend across seven production licenses. The iceberg ploughmarks are clearly seen from the survey, even though these marks are probably from previous glaciation age. However, it gives an intuitive feeling about the risk of iceberg scouring to the subsea pipelines.

Subsea Pipeline Design

Subsea pipeline is one of the main components of a subsea production system, see Fig. 5. It connects

production templates and transports the content (oil or gas) to floaters or onshore facilities. Following aspects shall be considered during the design process of a subsea pipeline system:

- Wall thickness
- Pipeline route selection
- Bottom roughness
- On-bottom stability
- Free spanning
- Expansion and buckling
- Tie-in system
- Cathodic protection
- Seabed intervention

The load and resistance factor design format (LRFD) is the preferred pipeline design comparing to traditional allowable stress design, which is depending on the safety class level

Iceberg Scouring,

Fig. 5 Subsea production system, with courtesy of SURF, Aker Solutions AS

(DNVGL 2017b). For other structural components, the allowable stress design is also used, such as the bend, valve, connector, etc. The principle of the LRFD method is to ensure that the design loads do not exceed design resistances for any of the considered failure modes in any load scenarios.

The pipeline integrity shall be checked against the iceberg scouring if the hazard does exist in the lifetime of pipeline in question. On the other hand, a risk assessment for the iceberg scouring is recommended, in which the probability for the pipeline exposed to iceberg scouring is considered. The combined risk is the product of exposure probability and the corresponding consequence. Comparing to the LRFD method, the risk assessment may give more detailed information about the iceberg scouring loads. An acceptable risk level has to be defined. The acceptable risk level can only be obtained with the approval from the oil and gas field operator. Thorough seabed mapping and detailed iceberg drifting data are required for making a reasonable risk level.

Seabed Types

There are quite a lot of ways to category the seabed soil types, such as ASTM D2487-17, 2017; BS 5930:2015 2015; and ISO 14688-2:2017 2017. Typical soil types are listed as follows:

- Clay
- Silt
- Sand
- Gravel

- Pebble
- Cobble
- Boulder

Among these types listed above, “sand,” “gravel,” “pebble,” “cobble,” and “shoulder” may behave in a similar fashion, while “clay” behaves quite differently. The property of “silt” depends on the particle size distribution. It can behave like “sand” or “clay.” Two main types of seabed, “sand” and “clay” are widely used for subsea engineering, see DNVGL (2017a). The subcategories for “sand” are “loose,” “medium,” and “dense.” The subcategories for “clay” are “very soft,” “soft,” “firm,” “stiff,” “very stiff,” “hard.” The simplified stiffness and the shear strength of each type are correspondingly defined. The soil types and stiffness are normally documented in geotechnical report of a subsea field development project.

The seabed soil in the Grand Banks offshore area is mainly composed of cohesionless soil, while the soil from Beaufort Sea is normally a cohesive soil. Nevertheless, the saturation of soil shall be considered (Barrette 2011).

Iceberg Scouring Mechanism

As mentioned earlier, the iceberg scouring becomes only interesting if it presents a hazard to the integrity of subsea structures, such as pipeline, protection structure, or template, etc. Consequently, the interaction involves at

Iceberg Scouring, Fig. 6 Iceberg scouring mechanism

least three major components: the iceberg, the seabed soil, and the subsea structure. Error! Reference source not found. Illustrates an ice keel scouring along the seabed soil and is about to in contact with the backfill of a subsea pipeline. The force generated by iceberg gouging the seabed could be significantly high. Palmer and Croasdale (2013) estimated that the force may reach 32 MN to cut a gouging 4 m deep and 40 m longer for a typical medium clay soil (shear strength 50 kPa). The force magnitude is much larger than the other design force. In order to protect the flowline, two methods are available. The first method is to trench seabed and bury pipeline with rocks (as shown in Fig. 6), and the other method is to shield the pipeline with protection structure, which could be used to absorb the impact energy from iceberg. Both methods are very expensive.

For the iceberg cutting the seabed soil, it is under combined loads from environmental loads and contact force either from seabed soil or subsea structure, see illustration in Fig. 6, the rigid body motion equations in 2D could be expressed as follows:

$$(1 + A_{xx})M\dot{V}_x + B_{xx}V_x = \sum_i F_{xi} \quad (2)$$

$$(1 + A_{zz})M\dot{V}_z + B_{zz}V_z = \sum_i F_{zi} \quad (3)$$

$$(1 + A_{xz})M\dot{\omega}_y + B_{yy}\omega_y = \sum_i F_{xi}a_{xi} + \sum_i F_{zi}a_{zi} \quad (4)$$

where A_{xx} , A_{zz} , A_{xz} are added mass factors on xx, zz, and xz direction, respectively. B_{xx} , B_{zz} , B_{xz} are damping factors on xx, zz, and xz direction, respectively. V_x , V_z , ω_y are iceberg velocity on x, z directions and rotation along y direction. F_{xi} are external forces on x direction which could due to current, wave, air, contact force or drag force from other ice features, etc. F_{zi} are external forces on z direction which could due to buoyancy, gravity, and contact force, etc. The soil can normally sustain very large strains and soil deformation, especially at the front mound (zone 1, the uppermost zone), as seen from Fig. 6. The calculation of the contact force between iceberg bottom and soil is

not straightforward, and the important parameters for calculating the contact force are the attack angle, the shear strength of the ice bottom, and soil. Croasdale et al. (2005) presented an analytical method by using the lower bound plasticity theory to calculate the contact force (vertical and horizontal). Mohr-Coulomb failure criterion is adopted for soil mass. Except for the analytical solution, reliable numerical simulation may give more detailed results for iceberg scouring (see next section).

The extent of soil deformation in Zone 2, the intermediate zone, is still uncertain. Further, the existence of subsea pipeline makes the problem more complicated, see Fig. 6. For the buried pipeline case, the bury depth (BD) is the most important parameter.

Design of BD by RMRS

As mentioned in previous section, the design bury depth (BD) is crucial. A large value of BD will definitely increase the cost of the project, for example, if the pipeline is buried in Zone 3, it may experience negligible soil deformation; however, the large BD makes it is not achievable at all. Pipeline in nowadays is often designed to be placed in Zone 2, where subgouging deformation exists. An optimized BD value can only be obtained by considering the soil and ice deformation into account, which is indeed challenging.

The rule by Russian Maritime Register of Shipping presents a thorough discussion of the subsea pipeline design under iceberg scouring loads (RMRS 2012). It requires that the pipeline is to be buried if there is evidence of ice gouging. Minimum BD must be set a distance of 1 m below the gouge depth. Safety factor (from 1.0 to 1.3) shall be multiplied with this distance, see Eq. 5.

$$B_D \geq G_D + Dk_0 \quad (5)$$

where B_D is bury depth, G_D is the design gouge depth, and D is a given “margin” (equal to 1 m), which can be decreased upon adequate justification. k_0 is a safety factor (from 1.0 to 1.3) based on the pipeline classification in the code (RMRS 2012). The value of design gouge depth could be approached from following methods:

- From seabed gouge data
- From statistical analyses
- From bathymetry and ice regime

Numerical Simulation of Iceberg Scouring

The numerical simulation of iceberg scouring is complicated due to following facts:

- The fluid structure interaction
- The soil and ice interaction
- The soil and structure interaction
- The large deformation of soil and ice
- Validation

The traditional Lagrange elements are not suitable for simulating the iceberg scouring problem. The main reason is that large deformation of soil is expected in the front mound area. Konuk and Gracie (2004) used so-called arbitrary Lagrangian-Eulerian (ALE) method to simulate the iceberg scouring, the buried pipeline was included in the model. A CAP plasticity constitute model was used to model the soil material. Nobahar et al. (2007) approached the iceberg scouring simulation by using the Lagrangian adaptive meshing technique which overcomes the large element distortion problem. A comparison with the conventional Winkler-type structural analysis was performed. Sayed and Timco (2009) presented a numerical model by using the particle-in-cell (PIC) advection scheme. It was a 2D model in which the iceberg was idealized as rigid indenter, see Fig. 7. Fadaifard and Tassoulas (2014) presented a new numerical model for the coupled seabed scour problem and its interaction with buried pipelines. The seabed was modeled as a viscous non-Newtonian fluid. The interface is achieved by level-set function. Large deformations are allowed. In all the numerical simulations mentioned above, the iceberg is assumed to be rigid, no failure of iceberg ice is allowed. This may produce over conservative scouring loads.

Mitigation Methods

If the iceberg scouring is indeed a design load, following mitigation methods for lowering the required bury depth can be used. In practical, all

Iceberg Scouring,

Fig. 7 Numerical scouring model by Sayed and Timco (2009), with permission of Elsevier

the mitigation methods shall be evaluated together with the economic cost.

following reports/studies found after the initial proposal.

- **Iceberg management**

The idea of iceberg management is to move the potential iceberg scouring risk away from the pipeline route. The monitoring of iceberg tracks and offshore towing vessels are needed.

- **Strong barriers besides pipeline**

The strong barriers can either be rock embankments or sheet piles. These barriers are used to stop the iceberg moving towards the pipeline and thus get rid of scouring. The barriers shall be strong enough to resist the ice features even if the icebergs may be accumulated over time.

- **Weak layer concept**

Palmer and Croasdale (2013) mentioned the so-called “weak layer” concept, in which a specially made layer is laid above the buried pipeline. It will deform significantly if an iceberg across the pipeline, but it will not transfer much shear stress downward. Thus, the pipeline is protected.

- **Cheese wire concept**

Din and Hafezparast (2015) proposed a “cheese wire” concept for protecting the pipeline against the iceberg scouring. It is designed to cut the iceberg bottom by an installed wire system besides the pipeline. However, no

Ice-Induced Vibration

Definition and Influence of Ice-Induced Vibration

When a ship sails through the ice area, it will inevitably collide with the ice-water mixture. The alternating load generated by crushing the moving ice and its impact on the structure causes the hull vibration, which is called ice-induced vibration (Huang 2004). For a long time, ice-induced vibration was considered a unique phenomenon of slender structures. However, in 1986, the large-scale oil drilling caisson platform Molikpaq was almost destroyed by ice-induced vibration in the Beaufort Sea in 1986, making the dynamic effect of ice on the structure attracting the attention of researchers (Fig. 1).

Ice load is the main environmental load that affects the safe operation of marine structures in ice areas. The ice-induced vibration caused by ice load inevitably causes damage to the hull structure. At first, continuous ice-induced vibration aggravates the fatigue damage to the structure and seriously affects the safety of the hull structure. Secondly, severe ice-induced vibration damages the internal equipment of the hull, such as breaking the upper and lower pipelines and loosening up the flanges. Moreover, it will also influence the comfort and health of the staff.

Research Methods of Ice-Induced Vibration

At present, the ice-induced vibration of the structure is mainly studied through field test,

indoor experiment, and numerical simulation (Wang 2019).

Field Test

The scope of ice-induced vibration research depends on the collection and analysis of field data to a great extent.

In the winter of 1971–1972, the Norstromsgrend lighthouse was observed to undergo violent vibrations after the interaction of sea ice (Eivind 2014). The staff carried out monitoring work on the vibration of the lighthouse. The maximum vibration acceleration generated by the lighthouse was 0.1 g, and the frequency was about 2.8 Hz. In 1998, Jefferies and Wrigh published an article based on the ice vibration phenomenon of the Molikpaq platform. The article stated that the ice-induced vibration caused the fatigue of the sand core and reduced the structure's ability to withstand ice loads. After that, marine structures deployment in ice areas usually needs to be equipped with related monitoring systems. For example, the Bohai JZ20-2 MUQ cone jacket platform is equipped with a complete ice-induced vibration three-dimensional monitoring system. The monitoring system mainly includes sea ice image monitoring, radar image monitoring, load plate and vibration acceleration sensors, etc. It monitors the sea ice parameters such as ice speed, ice thickness, ice direction, sea ice density, and structural ice load and vibration acceleration for long time which provides a large amount of field measured data for ice-induced vibration research.

Indoor Model Experiments

Indoor model test is also an important method for studying structural ice-induced vibration. As compared to the field tests, during indoor experiments, there is flexibility to change sea ice parameters and to obtain accurate measurement results. The Norwegian University of Science and Technology (NTNU) carried out an ice shock steady-state model test at the Hamburg Ice Pool (HSVA) in Germany. The ice speed range that may cause steady-state vibrations is determined by employing a mobile device to change the ice speed, moving frequency and amplitude (Hendrikse et al. 2012). Tianjin University has built the only indoor ice pool in China, which can be used to test the model response under different ice directions and speeds and to measure the propulsion resistance of ships in the ice area so as to study the characteristics of ice-induced vibration and the propulsion resistance of ships (Fig. 2).

Numerical Simulation

Due to the complexity of the sea ice-ocean structure interaction process, it is difficult to analyze the impact of different parameters on the vibration of the ocean structure through field tests and indoor experiments. Numerical simulation methods can accurately change the calculation parameters and have the advantages of low cost and high efficiency for understanding and analyzing the sea ice-structure interaction mechanism.

Based on the peculiarity of ice loads, new numerical methods are used to study the

Ice-Induced Vibration and Noise of Ships,

Fig. 2 Tianjin University indoor ice pool (<http://image.baidu.com/>)

interaction between sea ice and structure, including discrete element (DEM), bonded element (CEM), near-field dynamics (PD), and several other methods. Since sea ice mostly floats on the sea surface in the form of discrete fragments which has a strong discontinuity, therefore, when the sea ice collides with each other or interacts with the ocean platform structure, it will further break. At present, the sea ice model, based on DEM, is developing rapidly which can effectively simulate the breaking phenomenon of sea ice and can reasonably reflect the ice load characteristics of different structures. During analysis process, the hull at the waterline and the ice at the edge are regarded as discrete, and various load values at the contact point are calculated according to empirical formulas. It was found by Su et al. (2011) that the variation in simulated local ice loads was noteworthy even if the ice properties (ice thickness and ice strength) were fixed. Thereafter the variation in the contact and icebreaking patterns was taken as an internal source of the variation in local ice loads, than the external ice conditions.

Types of Ice-Induced Vibration

Dynamic properties of sea ice load are related to factors such as the strength characteristics and breaking characteristics of sea ice. The physical mechanism of ice-induced vibration has not yet been fully identified, and it mainly includes the

following two categories: forced vibration theory and self-excited vibration theory.

Forced Vibration Theory

The forced vibration theory of ice-induced vibration was first proposed by Peyton. It is believed that dynamic ice force has inherent frequency spectrum characteristics, and the change of ice force has nothing to do with structural conditions. Based on the field tests results in Cook Bay, Matlock et al. (1971) proposed a calculation model to predict the vibration of flexible structures caused by ice sheets. Starting from the displacement and elastic deformation conditions of ice sheets and structures, the interaction between the two was considered during study. The sea ice is regarded as elastic beams with equal spacing, and the beam spacing is the fracture length of the sea ice. The stepwise integration method is used to solve the equation of motion of the system under the action of ice force (Fig. 3).

Self-Excited Vibration Theory

The theory of self-excited vibration started when Blenkarm was monitoring the ice load on the Cook Bay oil and gas platform and found that the stress rate of sea ice increased with decrease in strength. This will lead to “negative damping,” which in turn causes self-excited vibration of the structure (Sodhi 1988). Self-excited vibration refers to a special vibration phenomenon that

Ice-Induced Vibration and Noise of Ships,

Fig. 3 Matlock model schematic

continuously accumulates energy inside the structure and increases amplitude. The occurrence of self-excited vibration depends on the strength of sea ice itself, and the movement of the structure is also an important prerequisite. When the self-excited vibration theory is used to describe the structural vibration caused by ice, it describes the relationship between the response of the structure and the change process of change in ice force and the relationship between the uniaxial compressive strength of ice and the rate of acceleration.

Characteristics of Ice-Induced Vibration of Marine Structures

According to the different characteristics of structural response at different ice speeds, ice-induced vibration can be divided into the following three types (Li 2010): the quasi-static response, the steady-state vibration response, and the random vibration response. The probability of steady-state vibration is small, but the structural vibration is very violent when it occurs, which is very harmful to marine structures. The amplitude of random vibration response at fast ice speed is not as high as that of steady-state vibration, but it is the most common type. This type of vibration should be considered during fatigue analysis of ice-induced vibration, whereas the quasi-static response does not cause the dynamic response of the platform.

The Quasi-Static Response Mode

The quasi-static mode occurs when the ice speed is very slow (generally less than 0.02 m/s) and the ice surface is relatively flat. In this case, the loading of ice force can be regarded as a static force, and the dynamic effect can be ignored.

The Random Vibration Response Mode

When the ice speed is fast, the sea ice acts on the ocean structure to compress and fracture it quickly and continuously. The sea ice is compressed into pieces of different sizes. The irregularity of the sizes of the sea ice causes the randomness of the force change period. Therefore, marine structures experience random vibrations in dynamic response.

The Steady-State Vibration Mode

Steady-state vibration is a type of severe vibration with constant period and constant amplitude. The occurrence of steady-state vibration needs the conditions of a fixed ice speed. From the field data, the steady-state vibration mostly occurs at the flat tide level. At this time, the ice speed is generally 0.02–0.04 m/s. From the analysis of the ice and platform interaction process, the cause of steady-state vibration is found to be due to the equal structural vibration speed and the ice speed. This causes the structure and ice to form a cyclic loading in a vibration period of the structure, thereby controlling the change in period of the compressive ice force, and the change in frequency of the ice force is controlled at the natural frequency of the structure. When the steady-state vibration occurs, the structural response is extremely violent, which will not only cause damage to the marine structure but also cause damage to the pipelines, flanges, and other equipment on the upper part of the marine structure in a very short period of time.

Control Methods of Ice-Induced Vibration

Studies have shown that sea ice is the main load of navigational objects in ice areas, especially in the construction of marine structures around the development of oil and gas resources in ice areas. This is the reason suppression of ice-induced vibration has become a new research topic. The traditional method of increasing the overall rigidity of the hull to strengthen the anti-icing vibration ability is often ineffective. Because of the huge investment in shipbuilding engineering, this method is not economical and difficult to implement (Zhang 2008). Structural vibration control technology has become a choice to solve this problem. The main strategies are divided into three categories: changing the characteristics of the vibration source, top isolation, and dynamic vibration absorption technology.

Changing the Characteristics of the Vibration Source

In comparison with the action mode of wave, wind load, and seismic load on the structure, position of the ice load is relatively fixed which only acts on the structure at the waterline. In

addition, the alternating ice load is formed by the ice destruction process during the interaction between ice and the structure. Therefore, different ice destruction forms will lead to different ice forces. Based on the form of the interface between the ice load and the structure, special devices can be set up to change the form of ice destruction and then change the force of ice acting on the structure.

Top Isolation

Top isolation technology can also be called base vibration isolation technology. Its vibration reduction principle is to isolate the energy that causes structural vibration by installing a vibration isolation support between the supporting member of structure and the upper system, so that the input energy is consumed on the vibration isolation layer before reaching the upper systems. In order to achieve a good vibration reduction effect, the vibration isolation device must have high strength (carrying capacity) and low rigidity (large deformation) mechanical properties.

Dynamic Vibration Absorption Technology

Dynamic vibration absorber has been proved to be one of the most efficient means of vibration reduction for a long time. Its basic design principle has been studied by many scholars, and it has been

widely applied in engineering practices. To solve the vibration problem of the anti-ice platform under the action of ice load, Wang Lingyu et al. (1996) studied the vibration reduction control of the platform by using a tuned liquid damper (TLD) and carried out field tests on the JZ20-2 MUQ platform and obtained very meaningful results (Fig. 4).

Ice-Induced Noise

Definition of Ice-Induced Noise

Ships sailing in the ice area will inevitably collide and impact with floating ice. The impact load of floating ice will excite the vibration of the hull and generate structural noise and air noise at the same time. The noise generated by the impact load of the floating ice is called ice-induced noise.

Influence of Ice-Induced Noise

Due to low temperature in winter, the sea surface of the harbor will be frozen. Generally, ships with icebreaking function will be used to assist icebreaking and berthing in the port area. To ensure the safety of merchant ships entering and leaving the port, tugboats are to sail in the ice area to ensure the smoothness of the channel. When a ship sails in through a floating ice area or breaks

Ice-Induced Vibration and Noise of Ships,

Fig. 4 Ice-resistant oil drilling platform (<http://image.baidu.com/>)

ice in an intact ice area, the hull is subjected to the impact load of the ice layer, and as a result it vibrates violently. At the same time, structural and air noises are generated which are the transient noises caused by the impact load of the floating ice. The noise is transmitted to the cabins along the hull structure and air, causing the noise of some cabins to increase sharply and seriously affecting the comfort of the ship and its crew. The research on transient noise of ships sailing in ice regions is of great significance for the comfort of ships planned to be developed in the future for polar regions.

Control Methods of Ice-Induced Noise

For reduction of ice-induced noise caused by transient excitation when colliding with ice floes, adding various noise reduction measures in the cabins can increase the comfort of the ship; however, it is not an economical option (Wu 2019). Therefore, keeping in view the ice-induced vibration, a centralized noise control technology is proposed to provide references for the noise control of ships sailing in polar ice regions.

Increase the Thickness of the Bow Plate

Increasing thickness of the bow plate can not only increase the strength of the bow but also efficiently resist the impact of floating ice. To a certain extent, it can suppress the transient noise generated during ice collision.

Arrange Stiffeners Orthogonally on the Bow

The simulation results prove that from the perspective of restraining the impact on the bow, stiffeners are arranged orthogonally, and the longitudinal direction is better than the transverse direction. From the perspective of controlling the transient noise of the cabin, the stiffeners are also arranged orthogonally, but the transverse direction is better than the vertical direction.

Laying Damping Materials

Laying damping materials can obviously suppress the transient high-frequency vibration which can control the bow impact response and cabin

transient noise. With the increase of the damping loss factor, the bow impact response and cabin transient noise under ice impact will gradually decrease.

The Rules of Ice-Induced Vibration and Noise

In order to obtain the rules of ship ice-induced vibration and noise, Pang Fuzhen (Pang et al. 2017) team carried out an icebreaker's vibration and noise measurement. The experimental ship type is the towed icebreaker work ship provided by Harbin Waterway Bureau. The test site was the Harbin section of Songhua River in Heilongjiang Province. The test temperature was $-2\sim 5\text{ }^{\circ}\text{C}$ and the ice thickness was measured as 40~50 cm, and the background noise was 45~50 dB (Figs. 5 and 6).

The experimental results obtained are as follows:

1. The ship trail test signifies that ice-induced load not only causes the low-order vertical vibration in the hull structure but also causes the local vibration in the ship.
2. During icebreaking operations, the vibration acceleration level in each area increased. Among them, the vibration acceleration along the length of the ship shows that it significantly increases at the bow, whereas at the midship it comparatively increases less. Increase at the stern is the lowest. In general, the ship's vibration response during icebreaking operations shows that the vibration at bow and midships is less, whereas in the engine room and stern area is more. The vibration response along the ascending direction at 1/4 of the length of the ship increases the most in the main deck area. The vibration in upper pilot area increases less, and in the cabin floor area, it increases the least. In general, the vibration response is the largest in the main deck area, slightly less in the driving deck area, and the lowest in the cabin floor area.
3. Icebreaking operations will have a certain impact on the habitability of various areas on

Ice-Induced Vibration and Noise of Ships, Fig. 5 Layout of the experimental ship cabin

Ice-Induced Vibration and Noise of Ships, Fig. 6 Ice-induced vibration and noise of ships

the ship. Among them, the vibration environment of the living area on the main deck, the upper pilot deck area, and the main deck fore and aft area are within the acceptable range of the human body. Only the vibration environment of the engine room floor area exceeds the acceptable range of the human body which becomes harmful.

- 4. During icebreaking operations, the noise of each cabin of the ship increases, but the noise of the cabins in different positions is different.
- 5. When the ship sails through ice area, noise of cabin of fore peak tank differs significantly along longitudinal direction. The noise change of living quarters of midship and steering

engine room in the stern region is less. When the ship navigates in open area, the noise of engine room is high; as a result, the change of noise of engine room is small when it sails in through ice area. For the cabin along draft direction, the noise change of cabin on the main deck is greatest, change of noise in cabin on the driving deck is lesser, and change of noise in living quarter of hull bottom is the least. In a word, when the ship sails through ice area, the cabin noise of engine room is still the most.

6. During icebreaking operations, the noise in some cabins exceeds the standard limit value, which affects the comfort of the ship. Therefore, in order to obtain a more comfortable experience, certain noise protection measures must be taken to reduce noise harmful effects.

Definition

Maritime transport is considered as one of the most important human activities throughout history. It is one of the foundations of globalization, communication, international standardization, and trade liberalization (Kumar and Hoffmann 2002). Countries can be barely isolated from the economic activities of other countries due to the technological and economic impact. In fact, countries nowadays are seeking for the opportunity for economic growth by opening their borders and markets to attract foreign investment and trade. The globalization is irresistible.

The globalization has greatly increased the demand for goods movement so as the maritime transport. As the consequence, the energy consumption, environmental consequences, as well as the social impact that maritime transport brings to the world are unneglectable. They will be discussed in the following entries.

Economic Impact of Maritime Transport

Globalization addresses more demands of good transportation, and the goods movement has a number of energy and environmental impact. For example, the transportation sector generates the largest share of greenhouse gas emission,

which is nearly 28.5% of 2016 greenhouse gas emissions (Environmental Protection Agency 2018). Furthermore, the survey conducted by European Environment Agency in 2017 indicates the maritime transportation is responsible for 12.8% of total greenhouse gases (GHG) emission.

Shipping is considered as the most energy-efficient one, and the international shipping industry is responsible for the carriage of around 90% of the world trade. However, the fuel costs represent as much as 50–60% of total ship operating costs depending on the type of ship and service. There are over 40,000 active vessels that transport cargo around the world. According to the survey of International Energy Agency, those global shipping fleets are responsible for around 2% of the world's annual fossil fuel consumption (Fig. 1). Thus, there is a strong economic motivation to employ technologies that can reduce the fuel consumption as well as the GHG emission.

To reduce the energy consumption from maritime transportation, not only many regulations have come into force, for example, Ship Energy Efficiency Management Plan (SEEMP) and Energy Efficiency Design Index (EEDI), but also more sea areas are being declared as Emission Control Areas (ECA). Furthermore, the requirement of passing through ECAs gets harsher over time. Besides the regulations, shipping markets have employed more energy-saving measures.

Impact of Maritime Transport, Fig. 1 Source of GHG and share of transport GHG emissions (European Environment Agency 2018)

According to the shipping market survey conducted by DNV-GL (2015), the shipping companies selecting measures for energy saving mainly base on financial considerations. Nine simple energy-saving measures have been commonly addressed such as hull and propeller cleaning, slow steaming, voyage planning optimization, etc. Still, many of them do not realize the expected saving. Most of the shipping companies underestimate the share of fuel costs in total shipping cost. Cost is the key element for efficiency.

Environmental Impacts of Maritime Activities

The environment impacts from international shipping are several such as greenhouse gas emission and acoustic and oil pollution (Wikipedia 2018), and they can be summarized in different contexts. For example, considering the sources of pollution from shipping, they can be categorized into liquids such as oil spills, solids such as garbage, and air such as greenhouse gas.

The air pollution from ships is the best understood, which is evidenced by the international conventions and national regulations, and reducing the air pollutant emissions from shipping is the key to avoid the most catastrophic impacts of climate change. The CO₂ and other climate pollutant emissions are still increasing. According to the survey conducted by ICCT (2017), the total shipping CO₂ emissions increased 2.4% from 2013 to 2015. Three ship classes accounted for 55% of the total shipping CO₂ emissions, container ships (23%), bulk carriers (19%), and oil tankers (13%). CO₂ is not the only pollutant from ships. Other pollutants such as sulfur dioxide (SO₂), nitrogen dioxide (NO_x), as well as particulate matter (PM_{2.5}) are also considered to contribute to climate change. Air pollution from international shipping accounts for approximately 50,000 premature deaths per year in Europe, at an annual cost to society of more than €58 billion (European Federation for Transport and Environment 2018).

Air pollution from ships continues to increase as the sector grows. According to IMO

greenhouse gas study, the nitrogen dioxide increased by 3.5% between 2013 and 2015, while the sulfur dioxide increased by 1%. The shipping emission can be driven by a number of factors such as the growing number of the international fleet, the more powerful engines, and the speeding up of ships. To reduce the emission from ship, one way is to improve the energy efficiency and develop alternative energy sources.

Sound pollution from ships can also harm the marine species who may rely on sound for reproduction. Growing levels of noise pollution in the ocean could drive fish away from their habitat into their death. For example, baby reef fish use sounds made by fish, shrimps, and sea urchins as a cue to find coral reefs (Simpson and Jeffs 2011). With human noise pollution from ships, this crucial behavior is coming under threat.

Social Impact of Maritime Industry

Social impacts are effects on individuals, communities, and society. There are many potential social impacts of maritime sectors. Employment can be considered as one of the most important means. Maritime sectors help to generate significant quantities of jobs. According to the ICS and BIMCO report, the global supply of seafarers in 2015 was estimated at 1,647,500, of which about 774,000 are officers and 873,500 are ratings. It can generate significant social benefit.

Another social impact when it comes to maritime industry is the public safety. The safety of vessels is critical to the global economy. According to the 2017 review conducted by Allianz Global Corporate & Specialty (AGCS), the number of shipping losses during 2016 is up to 85. Cargo vessels (30) account for more than a third of 2016's losses. The loss of a large container ship or cruise ship in environmentally sensitive waters could cost billions of dollars. The potential cost could be wreck removal, cargo liabilities, oil pollution, etc.

Piracy threat and the cyber threat should not be underestimated. Pirates attacked 43 ships and captured 58 crews during the first quarter of 2017, slightly up year-on-year. The introduction

of armed guards onboard vessels and the presence of a multinational naval task force successfully reduce the threat of pirates. With the development of autonomous ships, ships are increasingly dependent on IT services, such as Automatic Identification System (AIS), Global Positioning System (GPS), or other onboard control systems which are controlled through wireless network. Cyber threat may result in the disruption from technical failure or serious maritime event such as collision or other damage. According to the Draft IMO Guidelines Cyber Risk Management, to manage cyber risk, five steps are recommended to follow: identify, protect, detect, respond, and recover (IMO 2017).

Energy Efficiency Measures to Reduce Emissions from Shipping

The energy consumption of maritime transport mainly comes from the combustion of fuel oil from ships. The emission comes from the exhaust gas generated after combustion. A ship's fuel consumption rate is an indicator that comprehensively reflects the potential of energy saving and emission reduction technologies that can be applied on the ship. First, a ship's own performance can determine her energy-saving and emission reduction strategies. For example, the status of main and auxiliary engines of different ships, paint primer and sewage conditions, operating years, models, and hull immersion volume define the ship's energy conservation and emission reduction. The main auxiliary machine of the ship is an important energy-consuming equipment and safety equipment in the ship transportation process. The higher the operating efficiency of the main and auxiliary machines, the higher the combustion efficiency of the ship. This factor could be used to develop technologies to increase the ship's engine operation efficiency, leading to reduction of the ship's fuel consumption and emissions. Furthermore, the degree of wear of a ship's main engines varies along the ship's service period. For an aged ship, her main engine wears a lot, and its unit fuel consumption also increases. It will affect energy utilization efficiency and

pollutant discharge of the main engine. The power provided by a ship's main engine will be used to overtake the ship's resistance to move forward. A ship's resistance in her actual operational environment also has significant impact to a ship's energy performance. Technologies used to lower a ship's resistance through better design, construct, and operation are also extremely important to reduce negative environmental impacts from shipping industry. For example, a ship's encountered sea weather conditions significantly affect a ship's energy consumption and air emissions. When operated in harsh sea environment, the ship's running resistance will increase dramatically, resulting in large increase of the ship's main engine load. It means more fuel consumption and exhaust gas emissions. In addition, when sailing at higher altitudes, due to lower air pressure and lower oxygen content in the air, the combustion of the ship's fuel cannot be fully realized, resulting in a significant reduction in energy conversion efficiency. In order to ensure the normal operation, the main engine has to burn more fuel consumption to keep the ship's sailing safety. The geographical environment will also affect energy consumption and exhaust emissions, such as channel crossing, channel bending angle, channel depth, and channel width. In the case of the same other conditions, having a relatively small channel curvature will reduce the proportion of fuel consumption.

Furthermore, capital investment and economic benefits can also affect a ship's energy efficiency. For the newbuilding ships, the effect of implementing energy consumption and emission reduction technologies can be reflected by the cost of ship capital investment and the level of benefits. When shipbuilding enterprises make high-efficiency and low-cost inputs, they can promote the implementation of low-cost and high-efficiency of ships, thus achieving the realization of energy-saving and emission reduction effects. When shipyards make higher cost inputs, they will lead to lower economic benefits and may also make the yards generate negative economic benefits. It in turn reduces the enthusiasm of shipbuilding enterprises for energy conservation and emission reduction. The economic benefit of

Impact of Maritime Transport, Fig. 2 Overview of strategies to improve a ship’s energy efficiency from life cycle perspectives

a shipyard refers to the ratio of product input in the operation of the ship. The level of its benefits affects the entire shipbuilding industry to a certain extent. The higher the economic benefit, the faster the development of energy conservation and emission reduction of ships. The same situation is also applied to ship owners/shipping companies, if the benefits of energy efficiency are to be claimed by them. Therefore, economic benefits are always one of the important factors affecting a ship's energy efficiency and emission reduction during a ship's whole service life, i.e., design, construction, operation, and wrecked stages.

In addition, shipping management is another important factor that can be used to maximize a ship (fleet) energy efficiency. The management factors mainly include the shipping companies' optimal planning of the shipping routes, the choice of ships to call the ports, training of crews, maintenance of ships, arrangement of ship cargoes, etc. Reasonable route planning can reduce unnecessary sailing time, avoid harsh sea conditions, reduce ship consumption, and achieve energy saving and emission reduction. Better planning strategy of ship calling port and optimal arrangement of calling port order can minimize ship in port and the docking time. By reducing unnecessary waiting time in port, anchoring conditions, a ship can be either maximumly utilized in cargo transport or sailing with low speeds, leading to a high energy efficiency in terms of unit cargo transported. Moreover, from a ship's long-term management perspective, a ship's energy efficiency will normally decrease in terms of her sailing time at sea. Good maintenance strategy can also help to reduce a ship's total resistance and increase her engine propulsions during her entire service time. It should be noted that any kind of benefits claimed by various energy efficiency measures can be only reached by the good implementation/operations from crew members. Thus, the training of crew members and human factors involved in a ship's life cycle operation process will finally determine the actual energy efficiency of a ship. Figure 2 categorizes a brief summary of all possible energy efficiency measures that can be used to increase a ship's energy efficiency.

In Situ Permeability Measured Using Piezo-penetrators

Dong Wang

Ocean University of China, Qingdao, China

Definition

Piezo-penetrator

The penetrometer with pore pressure transducers attached to the probe. It is used to obtain both the penetration resistances and pore pressure.

Introduction

Consolidation of soil is concerned frequently in geotechnical practices. The consolidation depends on soil permeability which may be measured through one-dimensional compression test in laboratory and/or in situ dissipation tests of piezo-penetrometers. The disturbance of soil sample is avoided in the in situ tests, which is especially appreciated by the offshore geotechnical investigations. The dissipation tests of two widely used penetrometers, the piezocone and piezoball, are introduced in this entry, followed by the interpretation of the testing data.

Background

Consolidation of clayey soil and then the settlement of footings depend on a fundamental soil property, permeability. Soil permeability can be measured in laboratory, of which the reliability becomes doubtful if soil sample undergoes moderate or serious disturbances. Compared with the one-dimensional compression test in soil laboratory, the in situ tests are carried out in natural soil, without the need to obtain (nominally) undisturbed soil samples for later testing in the laboratory. This is especially important for offshore practice, since the cost of obtaining high-quality samples for laboratory testing is very high, and the low shear strengths in the upper few meters of the seabed pose particular practical difficulties. In situ tests using piezocones or piezoballs have thus been developed during the last three decades to obtain the coefficient of consolidation c_v and then the coefficient of permeability.

The Dissipation Test of Piezocone

The cone penetrometer is argued to be the most widely used offshore site investigation tool. Traditionally, the histories of the cone resistance and frictional resistance along the sleeve are measured and recorded with the downward movement of the penetrometer. If the conical probe is equipped with a pore pressure transducer located just behind the cone shoulder, the pore pressure during

the entire penetration process and the subsequent dissipation test can be measured as well. It is assumed that the penetration is nearly under undrained conditions in clays, silty clays, or clayey silts, as the standard piezocones with project areas of 1000 mm^2 or 1500 mm^2 are displaced with a velocity of 20 mm/s . The dissipation test is conducted by halting a penetrometer at the targeted depth, and the variation of the pore pressure accumulated during the penetration phase is thus recorded. The so-called operative coefficient of consolidation, c_h , is deduced by matching the dissipation curve recorded with an analytical or numerical curve, in which both curves are expressed as a relationship between normalized dissipation time and normalized excess pore pressure. A representative numerical curve was proposed by Teh and Houlsby (1991), with the normalized time T^* defined as function of dissipation time t , diameter of cone shoulder D , and rigidity index of soil I_r and c_h :

$$T^* = \frac{c_h t}{(0.5D)^2 \sqrt{I_r}} \quad (1)$$

The normalized excess pore pressure indicates the ratio between the excess pore pressure recorded during the dissipation phase and its nominal initial value, for example, suggested by Sully et al. (1999).

Interpretation of the dissipation test is complicated by a number of factors related to the elastoplastic response of soils. For example, both the initial distribution of the excess pore pressure and the subsequent dissipation are affected by the preyield and plastic stiffnesses of the soil, the degree of overconsolidation in situ, and the extent of any consolidation during penetration. In the 1980s and 1990s, a number of simplified decoupled approaches have been proposed to tackle the penetration and dissipation phases separately: (a) The continuous penetration is regarded as an ideally undrained process, then cylindrical or spherical cavity expansion or the more sophisticated strain path method can be used to obtain the excess pore pressure at the end of penetration. (b) Dissipation around the cone belongs to the traditional consolidation problems which are solved using finite element or finite difference

approaches based on Biot's theory or Terzaghi-Rendulic consolidation theory (Lunne et al. 1997). The shortcoming of the Terzaghi-Rendulic theory is that the total stresses during the dissipation phase are assumed to be constant. Recently, large deformation finite element approaches were developed to simulate the entire "penetration-dissipation" process (Mahmoodzadeh et al. 2014).

The operative coefficient of consolidation c_h was found empirically to be much larger than c_v in most cases, and their relationship has remained unclear until recently. According to parametric study using the modified small strain and large deformation finite element approaches, Mahmoodzadeh et al. (2014) suggested that

$$c_h = \frac{3(1-\mu)}{(1+\mu)} \left(\frac{\lambda}{\kappa} \right)^\alpha c_v \quad (2)$$

where μ is the Poisson's ratio of soil, λ and κ are the slopes of the normal consolidation line and swelling line, respectively, and α is a fitting coefficient. A typical value of α may be taken as 0.75. The dissipation around the cone is mainly along the horizontal; however, c_h does not represent the "horizontal" coefficient of consolidation. When the value of c_v is available, the coefficient of permeability can be deduced from classic Terzaghi's consolidation theory.

The Dissipation Test of Piezoball

Except for cone penetrometers, a full-flow penetrometer with ball-shaped probe, termed ball penetrometer, has been used increasingly during the last decade, in particular in soft seabed sediments due to its advantages of larger projected area and minimal correction for overburden pressure (Kelleher and Randolph 2005). Similar to the piezocones, the ball penetrometer may be fitted with a pore pressure transducer at equator or mid-face of the probe. The piezoball with dual pore pressure transducers is another option.

Piezoballs and piezocones share similar procedures of penetration and dissipation tests. A limited number of in situ and centrifuge model

tests have been carried out for piezoballs, assisted by the large deformation finite element simulations (Mahmoodzadeh et al. 2015). The normalized dissipation curves of piezoballs were similar in shape to that of piezocones. However, the normalized dissipation time of piezoballs, T_b , depends not only on the ball diameter D_b , but also on the diameter of the shaft connecting with the ball probe, d , which can be expressed as:

$$T_b = \frac{c_h t}{D_b d I_r^{0.25}} \quad (3)$$

The definition of c_h in Eq. 3 is identical to that through Eq. 2. The shapes of the normalized dissipation curves in terms of the equator and mid-face of the spherical probe can be found in Mahmoodzadeh et al. (2015).

Key Application

The dissipation tests of piezo-penetrometers have been used in a few offshore projects to determine the in situ permeability of cohesive soils, as reported in Lunne et al. (1997).

Definition

Pipeline installation is a highly nonlinear 3D process (Trapper 2019), which involves coupled in-plane and out-of-plane phenomena, such as full pipeline-seabed interaction, lateral buckling, lateral stability under hydrodynamic loads, torsion, sideways walking, etc. If the laying of pipelines is finished prior to the arrival of the platform or encounters bad weathers, the pipelines need to be abandoned onto the seabed, and recovery and reinstallation of pipelines need to be carried out when the platform is available. In the *abandonment operation*, the A&R cable lowers a pipeline down to the seabed by a pull head and in the *recovery operation* lifts it up to the sea level (Wang et al. 2015).

Scientific Fundamentals

Installation of Risers and Pipelines

With the discovery of offshore oil fields in the shallow waters of the Gulf of Mexico during the late 1940s, offshore pipeline installation was invented. The first “offshore” pipeline in the Gulf of Mexico was constructed in 1954. Now, offshore fields are being discovered in water depths of 3,000 m, and the pipeline installation technology is keeping up. The most common methods of pipeline lay installation methods are:

- S-lay (shallow to deep)
- J-lay (intermediate to deep)
- Reel lay (intermediate to deep)

Shallow water depth ranges from shore to 150 m. Intermediate water depth is assumed to be 150–300 m. Deep water has water depths greater than 300 m. Offshore magazine produces a survey of most of the pipeline lay barges that work in the United States every year. This survey does not cover all the lay barges of all the countries that do offshore work, but it does cover the bigger international ones – Heerema, Saipem, Stolt, Technip, Allseas, McDermott, Global, and Subsea 7.

Other methods that have been used for pipeline installation are tow methods consisting of:

- Bottom tow
- Off-bottom tow
- Mid-depth tow
- Surface tow

Tow methods can be used for installing pipelines from shallow water depths to deepwater depths depending on the design requirements.

Pipeline Installation Design Codes

The most commonly used offshore pipeline installation codes are as follows:

- DnV OS F101 (Det Norske Veritas)
- API RP 1111 (American Petroleum Institute)
- ASME B31.4 – pipeline transportation systems for liquid hydrocarbons and other liquids
- ASME B31.8 – gas transmission and distribution systems

Lay Methods

S-Lay

The most common method of pipeline installation in shallow water is the S-lay method. A typical S-lay configuration is shown in Fig. 1 (Guo et al. 2014). In the S-lay method, the welded pipeline is supported on the rollers of the vessel and the stinger, forming the overbend. Then it is suspended in the water all the way to the seabed, forming the sagbend. The overbend and sagbend form the shape of an “S.”

In the S-lay method, tensioners on the vessel/barge pull on the pipeline, keeping the whole section to the seabed in tension. The reaction of this pull is taken up by anchors installed ahead of the barge or, in the case of a dynamically

Installation and Decommissioning,
Fig. 1 S-lay configuration

positioned (DP) vessel, by thrusters. These barges/vessels are fitted with tension machines, abandonment and recovery (A&R) winches, and pipe-handling cranes. The firing line for welding the pipe may be placed in the center of the barge or to one side. The firing line consists of a number of stations for welding, nondestructive evaluation (NDE), and field joint application. The field joint station is located after the NDE station and the tension machines.

J-Lay

To keep up with the discovery of deepwater oil and gas fields, the J-lay system for pipeline installation was invented. In this system, lengths of pipe are welded in a near-vertical or vertical position and lowered to the seabed. The J-lay configuration is shown in Fig. 2 (Guo et al. 2014). In this configuration, the pipeline from the surface to the seabed is one large radius bend resulting in lower stresses than an S-lay system in the same water depth. There is no overbend, and a large stinger required in S-lay to support the pipe in deep water is eliminated. The horizontal forces required to maintain this configuration are much smaller than required for an S-lay system. This lends itself for DP shipshape vessels and derrick barges to be equipped with a J-lay tower.

The J-lay method is normally used in water depths greater than 150 m. These water depths

are normally too great for moored lay vessels to operate, because the required tensions and pipe bending stresses are too large.

Reel Lay

Reel pipelay is a method of installing pipelines in the ocean from a giant reel mounted on an offshore vessel, as shown in Fig. 3 (Smith and Clough 2010). Pipelines are assembled at an onshore spool-base facility and spooled onto a reel which is mounted on the deck of a pipelay barge. The first application of the reeled pipeline was on D-Day when the allies were supplied with fuel across the English Channel using a small diameter pipeline unreeled from a vessel. Commercial application of reeled pipeline technology was not available until the early 1970s when Santa Fe Corporation built the first reel vessel.

Reel technology also provides a safer and more stable work environment, thus speeding pipeline installation. Reeled pipelines can be installed up to 10 times faster than conventional pipelay. The greater speed allows pipelines to be laid during a short weather window. This can extend the normal construction season. Reel pipelay can be used on pipelines up to 457.2 mm in diameter.

The reel method reduces labor costs by permitting much of the welding, X-raying, corrosion coating, and testing to be accomplished onshore, where labor costs are generally lower than

Installation and Decommissioning,
Fig. 2 J-lay configuration

Installation and Decommissioning, Fig. 3 Seven oceans general arrangement of reel lay

comparable labor costs offshore. After the pipeline is reeled onto the drum of the pipe-laying vessel, it is taken to the offshore location for installation. The reeled pipeline can be installed in an S-lay method or J-lay method depending on the design of the reel vessel and the depth of water. Reel vessels can have vertical reels or horizontal reels.

Horizontal reel vessels lay pipelines in shallow to intermediate water depths using a stinger and S-lay method. The station keeping of vessels with horizontal reels can be done by anchors or DP.

The vertical reel vessel can normally install pipelines from the intermediate water depths to deep water, and station keeping is always DP. For deep water, the J-lay configuration is used and no stinger is required.

The pipe is unreeled, straightened, devalized, and connected to the wire rope from the seabed preinstalled holdback anchor. The sagbend stresses are controlled by the tensioning system on the reel vessel. The vessel moves ahead while it

slowly unreels the pipeline from the drum. When the end of the pipeline on the drum is unreeled, a pull head connected to a wire rope is attached. The end of the pipeline is lowered to the seabed by paying out the A&R wire rope from the reel vessel slowly in a controlled method always maintaining sufficient tension in the pipeline. A buoy is attached at the end welded pipeline on the reel drum. On returning, it pulls the end of the pipeline using the A&R cable, removes the pull head, and welds it to the pipeline on the drum. It then begins the unreeling process again.

The main disadvantages of the reeling method are the following:

- Connecting the ends of the pipeline segments.
- Amount of time to re-reel the pipeline to remove a buckle.
- Establishing a spool base close to the location where the pipeline is to be laid.
- Concrete-coated pipelines cannot be reeled.
- Only specifically designed pipe-in-pipe pipelines can be reeled.

- The pipeline is plastically deformed and then straightened. Some thinning of the wall and loss of yield strength of the material in localized areas can occur (Bauschinger effect) on the A&R cable. The reel vessel returns to the spool base to load more.

Tow Methods (Guo et al. 2014)

In the tow methods, the pipeline is normally constructed at an onshore site with access to the water. These methods can be used for installing pipelines across inland lakes, across wide rivers, and offshore. In the case of an offshore pipeline, the advantage of these methods is that the pipeline is welded onshore with an onshore pipeline spread. Once the pipeline is complete and hydrotested, the pipeline is dewatered and moved into the water, while being attached to a tow vessel (a large anchor handling vessel). It is then towed to a location offshore where each end is connected to pre-installed facilities. This could be cheaper than using a lay barge spread to install the pipeline offshore. The advantage occurs mainly if several small lines need to be laid and can be bundled inside a larger pipe. However, a case-by-case analysis is required to determine the risk versus the reward. The pipeline can be made up either perpendicular or parallel to the shoreline.

For a perpendicular launched pipeline, a land area that can accommodate the longest section of the fabricated pipeline must be leased. A launchway consisting of a line of rollers or rail system needs to be installed leading from the shore end right into the water. First, all the sections that make up the pipeline are fabricated and tested. Then, the first section of pipeline is lifted by side booms and placed on the rollers on the launchway. The cable from the tow vessel is attached, and the section is pulled into the water, leaving sufficient length onshore to make a welded tie-in to the next section. In this manner, the whole single pipeline is fabricated and pulled into the water. A holdback winch is always used during these pulls to maintain control and, if need be, to reverse the direction of pull.

In the parallel launch method, the land area acquired along the shore is normally the total

length of the pipeline to be towed. This could be longer than that acquired during perpendicular launch. No launchway is needed. After the sections of the pipeline are welded and tested, the sections are strung along the shoreline. The pipeline sections are welded together to make up the length of pipeline to be towed. The completed pipeline is moved into the water using side boom tractors and crawler cranes for the end structures. The front end is attached to the tow vessel, while the rear end is attached to a holdback anchor. The anchored tow vessel winches in the tow cable in such a manner that it gradually moves the pipeline laterally into the water, while the curvature is continuously monitored. When the whole length of pipeline and its end structures make one straight line, the tow vessel begins to tow the pipeline along the predetermined tow route. For pipelines that are to be towed into deep water, pressurized nitrogen can be introduced into the pipeline to prevent collapse or buckling under external hydrostatic pressure. A depth of 900 m can be achieved. Greater depths would require a stop for another recharge of pressurized nitrogen from the surface. This has never been done.

Bottom Tow

As the name indicates, the bottom tow method pulls the pipeline along the seabed to its final location. The length of a single section of pipeline is limited by the available bollard pull of the vessel used. The bollard pull must be greater than the total submerged weight of the pipeline, plus the partially submerged weight of the end structures, times the friction coefficient of the soil. For an estimate, the initial friction coefficient is taken as unity. Two to three vessels can be used in tandem to obtain additional bollard pull capability.

The ends of a bottom-towed pipeline are normally connected by deflect-to-connect method. In this method, the end sections of the pipeline are made to float a few feet above the seabed by providing additional buoyancy for this length and attaching anchor chains at discrete spacing along this length.

The buoyancy and chains are attached onshore with chains strapped over the buoyancy

pipe during towing and deployed at the pipeline's final location. This length can then be pulled laterally by attaching cables to the end of the pipeline from the facility. Once the pipeline end structure is secured at the facility, the connection can be made by flanges (in diving depth) or by hydraulically activated connectors (in deep water).

The disadvantages of bottom tow are the following:

- An extensive bottom survey along the tow route is required.
- The route must not cross existing pipelines. Otherwise, additional costs will be incurred for installing and removing structures to protect existing pipelines.
- Subsea transponder systems are required to locate the pipeline during tow and to place it in its final destination.
- The pipeline lying along the beach or near-shore can be subjected to large wave forces from storms, and this could compromise pipeline integrity. A pipe anchor system is required on standby for this emergency.
- In crossing shallow water areas, a chase vessel is required to keep fishing vessels from crossing the bottom-towed pipeline.

Off-Bottom Tow

In the off-bottom tow method, the submerged pipeline is buoyant and floats above the seabed at a predetermined height during the towing. This is achieved in the same manner as described in the above section for connecting the ends of bottom-towed pipeline. The buoyancy and chains are attached in discrete modules for the length of the pipeline.

The advantage of this method over bottom tow is that existing pipelines can be crossed by placing concrete mats placed over these pipelines and allowing the hanging chains to drag over the mats. No extensive protection structure is required. However, buoyancy and chains are required for the entire length of the pipeline. If several pipelines are needed for field development, the buoyancy and chains can be recovered and used again.

Mid-depth Tow

In the mid-depth tow method, the entire length of pipeline is kept at a considerable height above the seabed during towing. To achieve this, discrete buoyancy, chains, and a large tension applied to the pipeline are required.

The tension is applied by two tow vessels pulling in opposite directions at each end of the pipeline. Once the pipeline reaches its desired height, the front tow vessel applies more thrust while the back tow vessel cuts back on its reverse thrust. A third vessel monitors the height of the pipeline in the middle by using a subsea transponder system. This vessel sends its signal to the two tow vessels, which see the height in real time and adjust their thrusts appropriately to keep the pipeline within the desired height range. This method is not suited for very long pipelines (greater than 4.8 km).

Surface Tow

Surface tow of pipelines is similar to mid-depth tow except that the pipeline will not require any chains. The two vessels, one at each end, keep the pipeline in tension while it is towed on the surface. Only a survey of the final pipeline route is required. This method can be used for shallow water. For deep water, a sophisticated controlled flooding and/or buoyancy removal system is required. Not many pipelines are installed by this method.

Abandonment and Recovery of Risers and Pipelines

The sketch of the SLWR abandonment and recovery operation is shown in Fig. 4 (Wang et al. 2015). In the process, the SLWR is put down to the seabed from the sea surface or lifted up from the seabed to the sea surface by pull head E which is hanged by the A&R cable of the installation vessel. In the abandonment and recovery system, there are the pipelines (it includes the lower section O-A, buoyancy section A-B-C, upper section C-D-E), the A&R cable which supplies the tension to the riser, and the installation vessel in

Installation and Decommissioning,
Fig. 4 SLWR abandonment and recovery operation

Installation and Decommissioning,
Fig. 5 Pipeline abandonment and recovery operation

which there is the A&R winch. The engineers control the tension and length of the A&R cable and the location of the installation vessel to conduct the abandonment and recovery of SLWR. Because in the abandonment and recovery processes, the riser is hung off by cable at the hang-off point, the two physical processes are also called one point lowering and lifting. The processes are mutually inversed and can be described by the same mathematical model. The mechanical behavior of the riser and the A&R cable should be analyzed for the installation safety.

A Simplified Mathematical Model of Pipeline Abandonment and Recovery in Deep Water

The sketch of the simplified pipeline abandonment and recovery operation is shown in Fig. 5 (Zeng et al. 2014). In the processes a pipeline is lifted up from the seabed to the sea surface or put down to the seabed from the sea surface by joint A. The two physical processes are generally called one point lifting and lowering.

On the problem the following simplifications are made based on offshore engineering

experience: the marine environment is stable, the seabed can be regarded as rigid plane, the lifting and lowering processes are slow, and the material of pipelines is isotropic and always in the elastic state. As shown in Fig. 6, the touchdown point (TDP, the point where the suspended pipeline contacts with the seabed) is located at the origin O of the Cartesian coordinate system, where T_0 is the resultant force at joint A, H_0 and V_0 are the horizontal force and the vertical force at the origin, w is the pipeline submerged weight per unit length, θ is the angle between the pipeline axis and the horizon, and θ_0 is the angle between the direction of T_0 and the horizon. The natural coordinate system is established along the pipeline. It is clear that the physical quantities of the pipeline are the functions of the arc length s . Taking a

short segment of the pipeline, as shown in Fig. 7, it is easy to deduce the basic governing differential equations.

The whole mathematical model (Zeng et al. 2014) for the pipeline abandonment and recovery is the following boundary value problem:

$$\begin{aligned} EI \frac{d^3 \theta}{ds^3} - T \frac{d\theta}{ds} + w \cos \theta &= 0, \\ \frac{dT}{ds} - w \sin \theta &= 0, \\ \theta(0) &= 0, \\ \frac{d\theta}{ds}(0) &= 0, \\ T(0) &= H_0 = T_0 \cos \theta_0, \\ \frac{d\theta}{ds}(L) &= 0. \end{aligned}$$

Definition

A submarine pipeline (also known as marine, subsea, or offshore pipeline) is a pipeline that is laid on the seabed or below it inside a trench. In some cases, the pipeline is mostly on-land but in places it crosses water expanses, such as

small seas, straits, and rivers. Submarine pipelines are used primarily to carry oil or gas, but transportation of water is also important. A distinction is sometimes made between a flowline and a pipeline. The former is an intrafield pipeline, in the sense that it is used to connect subsea wellheads, manifolds, and the platform within a particular development field. The latter, sometimes referred to as an export pipeline, is used to bring the resource to shore (https://en.wikipedia.org/wiki/Submarine_pipeline).

Introduction

Offshore pipelines transport hydrocarbon product and other fluids between subsea wells and in-field or onshore processing facilities. Offshore fields are being built in water depth exceeding 10,000 m and technology required for pipeline installation is demanded. Installation of pipelines constitutes some of the most challenging offshore problems.

Offshore pipelines, with an outer diameter ranging from 0.1 to 1.5 m, are commonly installed by laying from a vessel, using an S-lay, J-lay, or reel lay configuration. A less common installation of pipeline is the towing method where the pipeline is assembled on shore.

One major geotechnical issue for offshore pipeline is the assessment of the as-laid pipeline embedment, which is typically found greater than the penetration under static self-weight. Pipeline as-laid embedment has a strong influence on pipeline designs, such as on-bottom stability, lateral buckling, axial friction, heat transfer, and exposure to submarine slides.

The most commonly used installation methods are firstly outlined and then the evaluation of the pipeline as-laid embedment is introduced in this entry.

The most commonly used offshore pipeline installation codes are:

1. DnV OS F101 (Det Norske Veritas).
2. API RP 1111 (American Petroleum Institute).

Pipeline Installation Method

S-Lay

The most common pipeline installation method in shallow waters is the S-lay method. S-lay refers to an installation configuration in which the pipeline starts in a horizontal position on the vessel stinger and forms a characteristic S-shape on the way to the seabed, as shown in Fig. 1(a).

The suspended length of the pipeline is held by tensioners which are usually located on the ramp.

The stinger is a curved structure at the stern of the vessel and provides a controlled-shape transition from horizontal to inclined suspended section. The stinger shape is prescribed by setting the pipeline at designed angles and its length vary with water depth.

The pipeline leaves the stinger at a predefined angle, and the upper curved part of the suspended pipeline is known as overbend. Further down, the pipeline bends in the opposite direction and often the maximum curvature occurs closer to the seabed in the sagbend region.

The curvature in the sagbend is controlled mainly by tension, but excessive tension can be detrimental to the pipeline in the section over the stinger. An overly short stinger could result in excessive bending at the end of the stinger, which may result in buckling of the pipeline. In general, plastic deformation on either the stinger or the sagbend should be avoided in the design.

J-Lay

J-lay is an alternative installation method in which the pipeline leaves the vessel from a nearly vertical position (the actual J-lay tower angles vary between 0° and 15° from the vertical), as shown schematically in Fig. 1(b). A J-shape pipeline configuration is formed on the way down to the seabed. The horizontal tension required to maintain the pipeline configuration are much smaller than required for an S-lay system, and there is no overbend and a large stinger required in S-lay to support the pipeline in deep water.

A short support structure (stinger) below the holding point guides the direction of the pipeline close to the water surface. The tension is to

support the shorter suspended length and to control the pipeline curvature in the sagbend.

The J-lay method is usually adopted in the water depth greater than 500 m. Although J-lay is normally slower in laying speed than the S-lay, it is suitable for deep water region and has been projected to be capable of installing pipelines down to 3350 m of water (Faldini 1999). The positioning of the pipeline can be more precise by J-lay for the touchdown point is not that far behind the vessel comparing with S-lay. An additional benefit is that the lower tension in the pipeline on the seabed translates into shorter free spans.

Pipeline Static Penetration Resistance

The pipeline as-laid embedment has a significant influence on the lateral stability and also the axial resistance. Therefore, it is important to estimate it as accurate as possible, but there are many factors that complicate this.

It is known that the field observations of the pipeline as-laid embedment are much greater than the estimates in the consideration of the static pipeline self-weight in the calculation. The additional embedment during the laying process results mainly from two mechanisms: (1) the stress concentration in the pipeline touchdown zone (TDZ); (2) soil remolding and strength degradation due to cyclic movements of the pipeline during laying, which are discussed in the section "Lay Effects to Pipeline Penetration." However, the static pipeline penetration resistance should form the basis of the evaluation before more complicated factors are involved in.

Existing methods to evaluate the pipeline embedment can be grouped into empirical correlations and theoretical solutions. The more rigorous theoretical solutions are preferred in the calculations.

Sandy Soil

When the pipeline is laid on the sandy seabed that permeable relative to the pipeline laying rate, generally the as-laid embedment is low and the penetration process is mainly drained.

Installation of Offshore Pipelines, Fig. 1 Schematic diagrams of (a) S-lay and (b) J-lay

The pipe vertical penetration resistance, V_{ult} (force per meter), can be expressed in the following simple relationship:

$$\frac{V_{ult}}{D} = \frac{w}{D} \cdot k_{vp} \quad (1)$$

where k_{vp} is a plastic (secant) stiffness.

The pipeline dynamic motions during the laying process will lead to a lower value of k_{vp} , especially the lateral motions of the pipeline.

Clayey Soil

On the seabed comprising soft clayey soils with low permeability, the pipeline static penetration

resistance can be assessed using an undrained analysis. The vertical bearing capacity of shallowly embedded pipelines on undrained soil with uniform or heterogeneous strength profile can be predicted using plasticity solutions. The pipeline penetration resistance, V_{ult} , can be expressed in the power law relationships, shown as Eq. (2):

$$\frac{V_{ult}}{Ds_u} = a \left(\frac{w}{D} \right)^b \quad (2)$$

where s_u is the shear strength at the pipeline invert and the parameters a and b depend on the pipe-soil roughness and the shear strength gradient with depth. $a = 6.0$ and $b = 0.25$ have been suggested for design calculations (Randolph and White 2008). w is the pipeline invert penetration, and D is the diameter of the pipeline.

Due to the higher density of the seabed sediments relative to water, the contribution of the soil buoyancy to pipeline penetration resistance is significant, especially in the shallow depth. The overall resistance is, therefore, expressed as:

$$\begin{aligned} \frac{V_{ult}}{Ds_u} &= a \left(\frac{w}{D} \right)^b + f_b A_s \left(\frac{w}{D} \right) \frac{\gamma'}{Ds_u} \\ &= N_c + N_b \frac{\gamma'}{Ds_u} \end{aligned} \quad (3)$$

where $N_c = a\hat{w}^b$, $N_b = f_b A_s(\hat{w})$, and $\hat{w} = \frac{w}{D}$. A_s is the area of the pipe lying below mudline level, shown in Fig. 2. γ' is the effective unit weight of the soil. Factor, $f_b = 1.5$ for $\hat{w} = 1.5$, is introduced to account for local heave (White et al. 2010), which will increase the buoyancy force above that due to the pipeline embedment.

The pipe embedded area, A_s , is calculated by:

$$A_s(\hat{w}) = \begin{cases} \frac{D^2}{4} \left[\sin^{-1} \left(\sqrt{4\hat{w}(1-\hat{w})} \right) - 2(1-2\hat{w})\sqrt{\hat{w}(1-\hat{w})} \right] & 0 \leq \hat{w} < 0.5 \\ \pi \frac{D^2}{4} - \frac{D^2}{4} \left[\sin^{-1} \left(\sqrt{4\hat{w}(1-\hat{w})} \right) - 2(2\hat{w}-1)\sqrt{\hat{w}(1-\hat{w})} \right] & 0.5 \leq \hat{w} < 1 \\ \pi \frac{D^2}{4} & 1 \leq \hat{w} \end{cases} \quad (4)$$

Lay Effects to Pipeline Penetration

Pipeline as-laid embedment is essentially a function of the self-weight of the pipeline and the strength of the seabed, but is much complicated by the laying process. Two effects must be considered in designs:

1. Stress concentration in the TDZ. The pipe-soil contact stress in the vicinity of the touchdown point will exceed the submerged self-weight of the pipe and any contents.
2. Dynamic movements of the pipe during the laying process. Driven by the vessel motions and hydrodynamic loadings of the hanging pipe, the pipeline actually moves laterally and vertically in the laying process, which leads to the local softening of the seabed sediments and push the soil away to the side of the pipe

alignment. The net effects can lead to pipeline penetration that is an order of magnitude greater than estimated from static loading.

It is common to assess the separate effects of the touchdown stress concentration and the dynamic touchdown motion by applying multiplicative adjustments to the static embedment approach described previously. The as-laid pipe weight, p , is multiplied by a concentration factor

Installation of Offshore Pipelines, Fig. 2 Partially embedded pipeline

due to the catenary shape, f_{lay} , to yield the maximum anticipated vertical force between the pipe and soil, $f_{lay}p$. This maximum touchdown load is then used in a conventional bearing capacity type of calculation to assess the pipe embedment, w_{static} , based on the anticipated maximum static touchdown load. Dynamic lay effects are then accounted for by multiplying w_{static} by a dynamic touchdown factor, f_{dyn} , to finally reach the predicted as-laid embedment for lay effects.

Force Concentration in TDZ

During the pipe laying, whether by J-lay or S-lay, the contact stresses between the pipe and the soil in the TDZ is much higher than the submerged pipe self-weight. As schematically shown in Fig. 3, the degree of “over-stress” is affected by the water depth, z_w , the stiffness of the seabed, k , the bending rigidity of the pipeline, EI , and the effective tension in the pipeline in the touchdown zone, T_0 .

From a simple catenary solution, the horizontal tension may be expressed in terms of the water depth, z_w , hang-off angle, φ , and the pipe submerged weight per unit length, W' , as,

$$\frac{T_0}{z_w W'} = \frac{\cos \varphi}{1 - \cos \varphi} \quad (5)$$

Following Pesce et al. (1998), nondimensional controlling parameter, the characteristic length, λ , is introduced. This is expressed as:

$$\lambda = \sqrt{\frac{EI}{T_0}} \quad (6)$$

The seabed stiffness can be expressed in non-dimensional form as:

$$K = \frac{\lambda^2}{T_0} k = \frac{EI}{T_0^2} k \quad (7)$$

For horizontal tension of $T_0 > 3\lambda W'$, which is for most pipelines, parametric solutions for the static lay conditions were presented by Randolph and White (2008) from analytical solutions (Lenci and Callegari 2005) and numerical analysis using OrcaFlex all converge to unique design lines. The value of flay can be expressed approximately as:

$$\begin{aligned} \frac{V_{max}}{W'} &\approx 0.6 + 0.4K^{0.25} \\ &= 0.6 + 0.4 \left(\frac{\lambda^2 k}{T_0} \right)^{0.25} \\ &= 0.6 + 0.4 \left(\frac{EI}{T_0^2} k \right)^{0.25} \end{aligned} \quad (8)$$

Lateral Motions

Any lateral movement of the pipeline will generate lateral resistance, and hence a decrease in the available penetration resistance due to the interaction between vertical and horizontal capacity.

Installation of Offshore Pipelines, Fig. 3 Pipeline configuration during laying: (a) complete pipeline and (b) touchdown zone

An example response from centrifuge model tests to explore self-embedment under the action of small amplitude cyclic horizontal displacements under undrained conditions is shown in Fig. 4 (Cheuk and White 2011). The test shown used kaolin clay, with a sensitivity, S_p , of 2–2.5, significant embedment

occurs for cyclic horizontal displacements as low as $\pm 5\%$ of the pipe diameter. The vertical load was kept constant, but as the pipe embeds, the normalized load V/DS_u decreases. Eventually, the embedment stabilizes at a value that is more than six times that for static vertical loading.

Installation of Offshore Pipelines, Fig. 4 Pipeline embedment under cyclic horizontal motion: (a) cyclic horizontal displacements and (b) resulting cyclic horizontal loads. (Cheuk and White 2011)

Installation of Offshore Pipelines, Fig. 5 Pipe vertical cyclic response at shallow embedment. (Hodder et al. 2008)

Cyclic Vertical Motions

The component of vertical penetration resistance due to buoyancy become significant if the soil becomes heavily remolded, S_u decreases in Eq. 3. Buoyancy always acts upwards on the pipe, whereas the soil strength contribution opposes the pipe motion, there is always a compressive reaction between the pipe and the soil during shallow vertical cyclic motion as illustrated in Fig. 5.

At deeper embedment, when the soil is weakened by remolding, any soil that is displaced away from the pipe centerline by the dynamic motion will fall back, and the “trenching” mechanism is less effective. Instead, the dynamic motion will remold and weaken the soil, leading to increased settlement under the pipe self-weight.

Based on the back analysis of as-laid surveys, recent design guidance suggests that dynamic effects can be accounted for by multiplying the static embedment by an empirical dynamic embedment factor, f_{dyn} , where this factor is typically in the range of 2–10.

Introduction

Jack-Up Rig and Spudcan Foundations

Most offshore drilling in shallow to moderate water depths (up to around 150 m) is performed from self-elevating jack-up rigs due to their proven flexibility, mobility, and cost-effectiveness (CLAROM 1993). Today's jack-ups typically consist of a buoyant triangular platform supported by three independent vertically retractable *K*-lattice legs, each resting on a spudcan (Fig. 1a). Spudcans are typically 10–20 m in (equivalent area) diameter and generally saucer-shaped polygonal or quasi-circular foundations (see Fig. 1b).

Installation and Preloading

Prior to commencing jack-up operations, spudcans are routinely proof loaded by static vertical preloading to increase the size of the yield envelope in vertical, moment, horizontal load space and thus ensure they have sufficient reserve capacity in any extreme storm design event (ISO 2015). Typically preloading is accomplished by pumping seawater into holding tanks within the hull. This causes the spudcan foundations to penetrate into the seabed until the load on the spudcan is equilibrated by the resistance of the underlying soil.

Preloading is performed in three ways: (a) simultaneous (all-round) preloading where all legs are incrementally loaded together while the hull is held with minimal draught or air gap;

Installation of Spudcans, Fig. 1 Typical jack-up rig: (a) whole jack-up rig. (After Le Tirant 1979); (b) spudcan geometry. (After Menzies and Lopez 2011)

(b) leg-by-leg preloading where each leg is incrementally loaded separately by sequential filling selected ballast tanks; and (c) combination of both where leg-by-leg preloading is carried out up to 70~80% of the full preload and then all legs are loaded simultaneously to the full preload. The preload is generally maintained for 2~4 h.

For the preloading and installation stage, critical aspects include accurate prediction of the spudcan penetration resistance profiles including the final resting depth under the full preload and the extent to which a cavity will remain above the spudcan as it penetrates or the depth at which soil will flow back over the spudcan. The aim of this report is to discuss spudcan installation in single-layer clay and sand and layered soils, corresponding design approaches for assessing

spudcan penetration, and potential risks and mitigation measures. For each design approach, all the required soil strength parameters must be obtained from proper site-specific soil investigation data.

Spudcan Installation in Clay

Cavity Depth

Hossain and Randolph (2009a) identified three distinct mechanisms of soil flow around the advancing spudcan: (a) shallow failure with outward and upward flow leading to surface heave and formation of a cavity above the spudcan (Fig. 2a), (b) gradual backflow into the cavity

Installation of Spudcans, Fig. 2 Soil failure mechanisms. (After Hossain et al. 2014a): (a) shallow failure; (b) gradual backflow; (c) deep failure

(Fig. 2b), and (c) deep failure with fully localized flow around the embedded spudcan and unchanged cavity (Fig. 2c). At a certain stage of penetration, soil backflow is initiated, and the continual backflow gradually provides a seal above the spudcan and limits the cavity depth. The subsequent backflow continues below the limiting cavity depth and above the advancing spudcan (i.e., the initial cavity is not filled up by the backflow process; see Fig. 2c). For assessing spudcan penetration response, the depth of soil backflow or limiting cavity depth above the spudcan must first be evaluated.

Hossain and Randolph (2009a) proposed a design chart, along with algebraic expressions, to estimate the limiting cavity depth, H_{cav} , above the penetrating spudcan. For single-layer clay with undrained shear strength increasing with depth, H_{cav} may be estimated according to

$$\frac{H_{cav}}{D} = S^{0.55} - \frac{S}{4} \quad \text{where} \quad (1)$$

$$S = \left(\frac{s_{um}}{\gamma' D} \right)^{1-\frac{k}{\gamma'}}$$

where k/γ' is the ratio of shear strength gradient to soil effective unit weight. This equation is now implemented in the current offshore design guidelines ISO (2015). A deep localized failure mechanism occurs at a penetration of $0.7D \sim 1D$ beyond the onset of backflow.

Design Methods

Several design methods are used in the jack-up industry for predicting spudcan penetration resistance. In this report, three methods will be discussed including (a) the Skempton ISO method (Skempton 1951), (b) the Houlsby-Martin ISO method (Houlsby and Martin 2003), and (c) the mechanism-based Hossain-Randolph approach (Hossain and Randolph 2009a, b; Hossain et al. 2014a).

ISO methods: The vertical bearing capacity, Q_v , of a foundation in clay of uniform shear strength (undrained failure in clay) at a specific depth can be expressed as

$$Q_v = s_{ui} N_c A + \gamma' (A d + V_b) \quad \text{for } d \leq H_{cav} \quad (2)$$

$$Q_v = s_{ui} N_c A + \gamma' (A H_{cav} + V_t) \quad \text{for } d > H_{cav} \quad (3)$$

where V_t and V_b are as depicted in Fig. 3. For the Skempton ISO method,

$$N_c = 6 \left(1 + 0.2 \frac{d}{D} \right) \leq N_{cd} \quad N_{cd} = 9 \quad (4)$$

which is based on a rough spudcan base ($\alpha = 1$) penetrating clay of uniform undrained shear strength. For typical Gulf of Mexico shear strength gradients and spudcan dimensions, it

Installation of Spudcans, Fig. 3 Schematic presentation of general situation during spudcan penetration: (a) $d \leq H_{cav}$; (b) $d > H_{cav}$

was suggested that the relevant value of s_{ui} should be taken as the average shear strength over a depth of $D/2$ below the widest cross section (referred to herein as the spudcan base level; see Fig. 3).

For the Houlsby-Martin ISO method, N_c factors are those reported by Houlsby and Martin (2003), as tabulated in Annex E of ISO (2015). In addition, the local shear strength at the spudcan base level, s_{u0i} , should be used.

Hossain-Randolph design approach: Hossain and Randolph (2009a) and Hossain et al. (2014a) proposed a “mechanism-based” design approach, based on the soil flow mechanisms observed in model tests and LDFE analysis. For shallow penetrations, less than the limiting cavity depth ($d \leq H_{cav}$), Q_v can be calculated based on the shallow failure mechanism (see Fig. 2a) as

$$Q_v = s_{u0i}N_cA + \gamma'(Ad + V_b) \text{ for } d \leq H_{cav} \quad (5)$$

N_c factors for nonhomogeneous clay are expressed as

$$N_c = N_{c0} \left[1 + 0.161 \left(\frac{kD}{s_{u0i}} \right)^{0.8} / \left(1 + \frac{d}{D} \right)^2 \right] \text{ for smooth spudcan base } (\alpha = 0) \quad (6)$$

$$N_c = N_{c0} \left[1 + 0.191 \left(\frac{kD}{s_{u0i}} \right)^{0.8} / \left(1 + \frac{d}{D} \right)^{1.5} \right] \text{ for rough spudcan base } (\alpha = 1) \quad (7)$$

where N_{c0} is the bearing capacity factor for uniform clay, given by

$$N_{c0} = 5.69 + \frac{d}{0.2D} \left(1 - \frac{d}{2.85D} \right) \leq 9.2 \text{ for smooth spudcan base } (\alpha = 0) \quad (8)$$

$$N_{c0} = 6.05 + \frac{d}{0.22D} \left(1 - \frac{d}{3.65D} \right) \leq 10.2 \text{ for rough spudcan base } (\alpha = 1) \quad (9)$$

For deep penetration in excess of H_{cav} , back-flow occurs above the advancing spudcan, but leaving the original cavity largely unchanged (see Fig. 2b), and a deep localized flow-round mechanism is finally developed (see Fig. 2c). For $d > H_{cav}$, the vertical bearing capacity, Q_v , can be calculated according to

$$Q_v = s_{u0i}N_{cd}A + \gamma'V_t \text{ for } d > H_{cav} \quad (10)$$

The N_{cd} values were found to merge into a narrow band, regardless of strength non-

homogeneity (kD/s_{umi}) and spudcan base roughness (α), finally reaching a limiting ultimate value once the deep failure mechanism was established. A simple expression for N_{cd} was proposed, given by

$$N_{cd} = 10 \left(1 + 0.065 \frac{d}{D} \right) \leq 11.3 \quad (11)$$

This expression takes into account both the transitional stage between the onset of backflow and attainment of deep failure and the final stage with deep localized failure where the bearing capacity factor becomes independent of penetration depth.

These expressions were developed based on the large deformation finite element (LDFE) analyses results considering a simple elastic-perfectly plastic soil model. However, in practice, natural soils exhibit strain-rate dependency and also soften as they are sheared and remolded. Therefore, Hossain and Randolph (2009b) proposed an adjustment factor to modify the just discussed

design approach developed on the basis of ideal elastic-perfectly plastic soil behavior as

$$\frac{N_{c,adjust}}{N_c} \text{ or } \frac{N_{cd,adjust}}{N_{cd}} = \frac{(1 + R_b \mu)}{S_t} \left(1 + (S_t - 1) e^{-7.2/\xi_{95}} \right) \quad (12)$$

where N_c and N_{cd} are the capacity factors from Eqs. 6~9 and 11. The rate coefficient R_b ranges from 1.47 (rapid penetration during initial stages of preloading) to 0.77 (slower penetration during final stages) and essentially drops to zero (negligible rate effect) during additional settlement under the final preload.

If the values for pertinent parameters are available, bearing capacity factors, N_c and N_{cd} , may be adjusted following Eq. 12. Alternatively, in the absence of site-specific data, a 20% reduction is suggested to be applied to the vertical penetration resistance computed using Eqs. 6~9 and 11 (Menzies and Roper 2008; Hossain and Randolph 2009b). Example prediction profiles for a typical site in the Gulf of Mexico are shown in Fig. 4.

Installation of Spudcans,

Fig. 4 Example of prediction profiles from Gulf of Mexico site. (After Hossain et al. 2014a)

Spudcan Installation in (silica) Sand

Cavity Depth

In sand, soil backflow (flow from beneath the spudcan, around the spudcan edge, and finally above the spudcan) and inflow (caving in) into the cavity above the spudcan start to occur immediately after the widest cross section of the spudcan is below the ground surface. The backfill/infill sand would usually be assumed to rest at the angle of repose, which may be taken as approximately the critical state friction angle ϕ_{cv} (see Fig. 5). The cavity side is not vertical (or quasi-vertical) either. Instead, the slope starts from a distance of $0.3\sim 0.4D$ away from the vertical line. The volume of the backfill/infill sand should therefore be calculated accordingly.

Design Methods

Several design methods are used in the jack-up industry for predicting spudcan penetration resistance in sand. Three methods will be discussed including (a) the Martin ISO method (Martin 2003), (b) the Cassidy-Houlsby ISO method (Cassidy and Houlsby 2002), and (c) the White et al. approach (White et al. 2008).

ISO methods: Evaluating the penetration of a spudcan in silica sand in ISO (2015) is based on a drained bearing capacity calculation (no excess pore pressure is generated) and expressed as

$$Q_v = \gamma'(0.5DN_\gamma A + V_b) \quad \text{for } d \leq 0 \quad (13)$$

$$Q_v = \gamma'(0.5DN_\gamma A + dN_q d_q A + V_t - V_{soil}) \quad \text{for } d > 0 \quad (14)$$

where V_{soil} is the volume of the soil above the spudcan. For the Martin ISO method, N_γ and N_q values from Martin's ABC software should be used. These bearing capacity factors are for flat-based, rough circular footing. Cassidy and Houlsby (2002) tabulated N_γ factors as a function of cone angle, cone base roughness, and peak friction angle. For the Cassidy-Houlsby ISO method, N_q values should be picked from Martin's ABC. Depth factor of $d_q = 1 + 2 \tan \phi'(1 - \sin \phi')^2(d/D)$, as proposed by Vesic (1975), can be used.

White et al. approach: For the White et al. approach, the scale effect (i.e., essentially the stress-level effect) and progressive failure should be taken into account in order to select an operative friction angle for medium dense to dense sand. An iterative process is needed which involves the following equations together with Eq. 13 or 14

$$I_R = D_r(Q_{crushing} - \ln p') - 1 \quad (15)$$

$$\phi' = \phi'_{cv} + m I_R \quad (16)$$

$$p' = \lambda q_{nom} \quad (17)$$

$$p' = \left(\frac{1}{1 + \tan^2 \phi'} \right) \left(\frac{1}{1 + \sin \phi'} \right) \times \frac{q_{nom} + 3\gamma'd}{4} \quad (18)$$

where I_R is the relative dilatancy index, D_r is the relative density of sand, $Q_{crushing}$ is the particle crushing strength on a natural log scale, p' is the mean stress level at failure, m and λ are con-

Installation of Spudcans,

Fig. 5 Backfill/infill in sand

stants, and $q_{\text{nom}} = Q_v/(\pi D^2/4)$ is the nominal bearing pressure. The iterative approach is most simply achieved by assuming that $\phi' = \phi_{\text{cv}}$, picking N_γ and N_q values from Martin's ABC, and then applying Eqs. 13 or 14, 15, 16, and 17 in sequence, to find a new estimate of ϕ' . This process is repeated until satisfactory convergence is achieved. White et al. (2008) suggested $m = 0.85$ and 0.7 for equivalent enclosed cone angle of 150° and 130° , respectively, and $\lambda = 0.15$ based on back-analysis of the centrifuge test data.

Overestimation of penetration resistance:

For silica sands, using an appropriate mobilized friction angle (based on the relative density), overestimation of penetration resistance, in comparison with reported field data, often occurs. This is exacerbated when a relatively thin sand layer is sandwiched between two clay layers. This may be partly due to less than fully drained conditions in the sand layer, but the dominant factor is that the thickness of the layer relative to the spudcan diameter is not sufficient to mobilize the full capacity of the layer during penetration of a 10–20 m diameter spudcan. To cope with this issue, (i) SNAME (2008) suggests, based on experience with measured field data, reducing the (assumed) mobilized friction angle in the sand by $5\text{--}20^\circ$ (as low as 12° depending on the sand relative density, D_r), thus reducing the estimated penetration resistance; (ii) InSafeJIP (2011) suggests using a mobilization factor (multiplicative to the first term of Eq. 13 and first and second terms of Eq. 14; right-hand side) of 0.25–0.5. Lower values would be applicable to more compressible materials (e.g., carbonate sands) and higher values for stiffer materials, but little quantitative evidence exists.

Spudcan Installation in Layered Soils with Potential for Punch-Through: Stiff-Over-Soft Clay

Cavity Depth

Hossain and Randolph (2010a, b) identified mechanisms of soil flow around the spudcan advancing in stiff-soft clay deposits (discussed later). The cavity depth can be assessed as

$$\frac{H_{\text{cav}}}{D} \approx 1.4 \left\{ \left(\frac{s_{u1i}}{\gamma'_2 D} \right) \left(\frac{t_1}{D} \right) / \left(1 + \frac{k_2 D}{s_{u2si}} \right) \right\}^{0.5} \quad (19)$$

where s_{u1i} is the intact undrained shear strength of the first-layer clay, s_{u2si} is the intact undrained shear strength of the second-layer clay at the first–second layer interface, t_1 is the thickness of the first-layer clay, and γ'_2 and k_2 are the effective unit weight and strength gradient of the second-layer clay, respectively.

Design Methods

Two methods will be discussed including (a) the punching shear ISO method (Brown and Meyerhof 1969) and (b) the improved ISO method (Zheng et al. 2016). In both methods, penetration resistance is contributed by two main components: (a) end bearing resistance in the underlying soft clay layer and (b) frictional resistance in the upper stiff clay layer or in both layers.

ISO method: This method is applicable only for the stiff clay layer. For the punching shear ISO method, a cylindrical plug of diameter D is assumed between the base of the advancing spudcan and the stiff-soft layer interface. The plug base is assumed to be fixed at the interface regardless of the spudcan penetration, i.e., (i) the height of the plug reduces with the progress of spudcan penetration in the stiff layer ($t_r = t_1 - d$), and (ii) the movement of the plug in the underlying soft layer and the deformation of the layer boundary are restricted. These are the major shortcomings of this method. Figure 6a shows the analytical model. The vertical bearing capacity, Q_v , of a foundation in uniform stiff clay over uniform soft clay at a specific depth d can be expressed as

$$\begin{aligned} Q_v &= A \left\{ 4\eta \frac{t_r}{D} s_{u1i} + N_{csu2i} \right\} \\ &\quad + \gamma'_1 (Ad + V_b) \\ &\leq N_{csu1i} A + \gamma'_1 (Ad + V_b) \text{ for } d \\ &\leq H_{\text{cav}} \end{aligned} \quad (20)$$

Installation of Spudcans, Fig. 6 Conceptual models for spudcan at punch-through in stiff-over-soft clays: (a) ISO method; (b) improved ISO method

$$\begin{aligned}
 Q_v &= A \left\{ 4\eta \frac{t_r}{D} s_{u1i} + N_c s_{u2i} \right\} \\
 &\quad + \gamma'_1 (A H_{cav} + V_t) \\
 &\leq N_c s_{u1i} A + \gamma'_1 (A H_{cav} + V_t) \quad d \\
 &> H_{cav}
 \end{aligned} \quad (21)$$

The first term represents frictional resistance along the surfaces of the cylindrical plug, and the second term is due to end bearing of the underlying clay at the interface. It is assumed full shear strength was not mobilized around the periphery of the plug and hence a factor η is applied. A value of $\eta = 0.75$ (suggested by Brown and Meyerhof 1969) ~ 0.9 (proposed by Hanna and Meyerhof 1980) can be used.

For stiff-over-soft clay, $A \left\{ 4\eta \frac{t_r}{D} s_{u1i} + N_c s_{u2i} \right\} + \gamma'_1 (A d + V_b)$, N_c should be picked from Eq. 4 using $d/D = t_r/D$ (i.e., depth of the plug base) regardless of spudcan penetration depth. This is because end bearing is assumed to be mobilized at the interface. For single-layer clay, $N_c s_{u1i} A + \gamma'_1 (A d + V_b)$, N_c should be

picked from Eq. 4 using actual penetration depth of the spudcan base, i.e., $d/D = d/D$.

For bottom layer with nonuniform undrained shear strength, an average value over a depth of $0.5D$ can be used. For the bottom clay layer, the penetration resistance should be calculated using the single-layer method as discussed previously. The soil plug carried down with the spudcan from the upper layer, and corresponding contribution to the penetration resistance, is neglected.

Improved ISO method (Zheng et al. 2016): The improved ISO method was proposed by Zheng et al. (2016). This method is applicable for the penetration resistance of stiff and underlying soft clay layers and both uniform and nonuniform clay deposits. The depth of punch-through and peak resistance basically follows the original ISO method, but adding a plug (of height t_p) in the bottom layer and shifting the fictitious footing position to the base of the added plug, as illustrated in Fig. 6b. For spudcan penetration in uniform stiff-over-soft clay deposit ($s_{u2} = s_{u2i}$), it can be expressed as

$$Q_v = A \left\{ 3 \frac{t_r}{D} s_{u1i} + \min \left[6 \left(1 + 0.2 \frac{t}{D} \right), 9.0 \right] s_{u2} + \gamma'_1 (Ad + V_b) + 4.2 \frac{t_p}{D} s_{u2i} \right\} \text{ for } d \leq N_c s_{u1i} A + \gamma'_1 (Ad + V_b) \leq H_{cav} \quad (22)$$

$$Q_v = A \left\{ 3 \frac{t_r}{D} s_{u1i} + \min \left[6 \left(1 + 0.2 \frac{t}{D} \right), 9.0 \right] s_{u2} + \gamma'_1 (AH_{cav} + V_t) + 4.2 \frac{t_p}{D} s_{u2i} \right\} \text{ for } d > H_{cav} \leq N_c s_{u1i} A + \gamma'_1 (AH_{cav} + V_t) \quad (23)$$

To keep a simple form of the formulas, Eqs. 22 and 23 are also used to predict the peak resistance for spudcan penetration in uniform-over-nonuniform deposit (i.e., $k > 0$), taking s_{u2} in Eqs. 22 and 23 as the average strength over the depth of $D/2$ below the layer interface. Based on the calibrated data, the equivalent soil plug thickness t_p can be approximately given as

$$\frac{t_p}{t_r} = 0.53 \left(\frac{s_{u2i}}{s_{u1i}} \right)^{-0.5} \left(\frac{t_r}{D} \right)^{-1} \left[3 - \left(1.5 - \frac{kD}{s_{u2i}} \right)^2 \right]^{0.5t_r/D} \text{ for } kD/s_{u2i} \leq 3 \quad (24)$$

For spudcan penetration resistance in the bottom layer, a simplified single-layer approach is used (see Eq. 10), which implicitly incorporates the effect of the soil plug and corresponding additional resistance in the deep bearing capacity factor N_{cd} . The value of N_{cd} can be expressed as

$$N_{cd} = 9.8 + 1.3 \left(\frac{s_{subs}}{s_{ut}} \right)^{-1} \text{Min} \left[\left(\frac{t}{D} \right)^{0.5}, 1.0 \right] \left(1 + \frac{kD}{s_{subs}} \right)^{-1} \quad (25)$$

Spudcan Installation in Layered Soils with Potential for Punch-Through: Sand Over Clay

Cavity Depth

The volume of the soil above the spudcan, V_{soil} , can be calculated in a manner similar to single-layer sand.

Design Methods

Three methods will be discussed including (a) the load spread ISO method, (b) the punching shear ISO method, and (c) the mechanism-based Lee et al. and Hu et al. approaches (Lee et al. 2013a, b; Hu et al. 2015, 2018).

ISO methods: These methods are applicable only for the sand layer. The base is assumed to be fixed at the sand-clay layer interface regardless of the spudcan penetration. In the load spread method, the bearing capacity is calculated by considering a fictitious footing at the interface between the sand and clay layers with an area $A_p = \pi D_p^2/4$, where $D_p = D + 2t_r/n_s$. The applied load is spread with a gradient of 1(horizontal): n_s (vertical), with the load spread factor $n_s = 3$ to 5 recommended by ISO (2015). Hossain (2014) also confirms from centrifuge observations that, in silica sand, n_s can be taken as 3 (see Fig. 7). The analytical model is shown in Fig. 8. The vertical bearing capacity, Q_v , of a foundation in sand over clay at a specific depth d can be expressed as

$$Q_v = A_p N_c s_{u2} + \gamma'_1 (Ad + V_b) \leq \gamma'_1 (0.5DN_{\gamma}A + V_b) \text{ for } d \leq 0 \quad (26)$$

$$Q_v = A_p N_c s_{u2} + \gamma'_1 (Ad + V_t - V_{soil}) \leq \gamma'_1 (0.5DN_{\gamma}A + dN_q d_q A + V_t - V_{soil}) \text{ for } d > 0 \quad (27)$$

In this method, the contribution from the frictional resistance around the plug was neglected.

Installation of Spudcans, Fig. 7 Soil failure pattern for load spread factor. (After Hossain 2014)

Installation of Spudcans, Fig. 8 Conceptual model for spudcan at punch-through in sand-over-clay deposits (ISO method)

For the punching shear ISO method, similar to stiff-over-soft clay, a cylindrical plug of diameter D is assumed between the base of the advancing

spudcan and the underlying layer interface, with the base fixed at the sand-clay layer interface regardless of the spudcan penetration. As a

cylindrical plug is assumed, dilatancy of the sand is therefore neglected (dilation angle, $\psi = 0^\circ$). The vertical bearing capacity, Q_v , of a foundation in sand over clay at a specific depth d can be expressed as

$$Q_v = A \left(2t_r \gamma'_1 (t_r + 2d) K_s \frac{\tan \phi'}{D} + N_c s_{u2si} \right) + \gamma'_1 (Ad + V_b) \leq \gamma'_1 (0.5DN_\gamma A + V_b) \text{ for } d \leq 0 \quad (28)$$

$$Q_v = A \left(2t_r \gamma'_1 (t_r + 2d) K_s \frac{\tan \phi'}{D} + N_c s_{u2si} \right) + \gamma'_1 (Ad + V_t - V_{soil}) \leq \gamma'_1 (0.5DN_\gamma A + dN_q d_q A + V_t - V_{soil}) \text{ for } d > 0 \quad (29)$$

where K_s is the punching shear coefficient and ϕ' is the effective angle of internal friction. Theoretically K_s should lie in between at rest earth

pressure coefficient (K_0) and passive earth pressure coefficient (K_p). The values of K_s suggested by ISO (2015) and Hanna and Meyerhof (1980) are given in Fig. 9, as a function of ϕ' and $Q_{v,clay}/Q_{v,sand}$ (ratio of single-layer response for a surface spudcan on the clay layer and that on the sand layer).

N_c should be picked from Eq. 4. For bottom layer with nonuniform undrained shear strength, an average value over a depth of $D/2$ can be used. For the bottom clay layer, the penetration resistance should be calculated using the single-layer approach discussed previously.

Lee et al. and Hu et al. approach: Lee et al. (2013a, b) and Hu et al. (2015, 2018) proposed a mechanism-based design approach based on the soil flow mechanisms observed in model tests and LDFE analyses. The approach simplified the spudcan penetration profile as a combination of the peak resistance and post-peak resistance in the sand layer, q_{peak} and $q_{post-peak}$, and the resistance in the clay layer, q_{clay} . q_{peak} is the sum of the frictional resistance in the sand, the bearing

Installation of Spudcans,

Fig. 9 Bearing capacity ratio versus coefficient of punching shear

capacity of the underlying clay, and the weight of the sand frustum, and it is expressed as

$$q_{\text{peak}} = (N_{c0}s_{\text{umi}} + q_0 + 0.12\gamma'_s H_s) \left(1 + \frac{1.76H_s}{D} \tan \psi\right)^{E^*} + \frac{\gamma'_s D}{2 \tan \psi (E^* + 1)} \left[1 - \left(1 - \frac{1.76H_s}{D} E^* \tan \psi\right) \left(1 + \frac{1.76H_s}{D} \tan \psi\right)^{E^*}\right] \quad (30)$$

where N_{c0} is the bearing capacity factor for clay at the base of a circular foundation, which

$$q = \frac{\gamma'_s D}{E} + \left\{ \left[\left(14.8 \frac{d - 0.1H_s}{D} + 10.6\right) s_{\text{umi}} + q_0 + \gamma'_s H_s + (\gamma'_c - \gamma'_s)(d - 0.1H_s) - \frac{\gamma'_s D}{E} \right] \exp \left[\frac{E(H_s - d)}{D} \right] \right\} \quad (31)$$

where γ'_c is the effective unit weight of clay and E is also a parameter to simplify the algebra (Hu et al. 2018).

For the resistance in the clay layer, the bearing capacity is expressed as

$$\begin{aligned} q_{\text{clay}} &= N_c s_{u0i} + H_{\text{plug}} \gamma'_c \\ &= N_c s_{u0i} \\ &\quad + 0.9H_s \gamma'_c \quad \left(0.16 \leq \frac{H_s}{D} \leq 1.00\right) \end{aligned} \quad (32)$$

where s_{u0i} is the clay shear strength at the lowest level of the spudcan's widest cross-sectional area and H_{plug} is the height of the sand plug. The bearing capacity factor N_c was summarized from a sand overlying clay centrifuge testing database and LDFE analyses of the full penetration process, incorporating various footing shapes and soil conditions.

Spudcan Installation in Layered Soils with Potential for Squeezing: Soft Clay-Over-Strong Layer

Cavity Depth

If the thickness of the soft clay layer is relatively thin and hence the (limiting cavity depth in single

is obtained from Houlsby and Martin (2003); q_0 is the effective overburden pressure; and E^* is a parameter to simplify the algebra. The depth of the peak resistance in the sand layer is taken as $0.12H_s$, where H_s is the sand layer thickness.

For assessing spudcan penetration resistance after the peak failure in the top sand layer and before penetrating into the bottom clay layer, an analytical model was proposed as

layer of that clay + limiting squeezing depth) < (thickness of the soft clay layer), soil backflow can occur earlier due to the influence of squeezing (Hossain 2014). This means H_{cav} in soft-over-strong soils may be lower compared to that on single-layer soft clay.

Design Methods

For assessing spudcan penetration in soft clay-over-strong layer, four methods will be discussed including (a) the squeezing ISO method (Meyerhof and Chaplin 1953; Brown and Meyerhof 1969), (b) the Merifield-Nguyen method (Merifield and Nguyen 2006), (c) the Meyerhof and Hanna method (Meyerhof 1974; Meyerhof and Hanna 1978), and (d) the CLAROM method (CLAROM 1993).

Squeezing ISO method: This method is applicable only for the overlying soft clay layer. A uniform strength is considered for the top layer, and the underlying layer is assumed to be rigid. The penetration resistance in the soft clay layer can be assessed according to

$$\begin{aligned} Q_v &= A \left\{ 0.33 \frac{D}{t_r} s_{u1i} + (N_c - 1) s_{u1i} \right\} \\ &\quad + \gamma'_1 (Ad + V_b) \\ &\geq N_c s_{u1i} A + \gamma'_1 (Ad + V_b) \quad \text{for } d \\ &\leq H_{\text{cav}} \end{aligned} \quad (33)$$

$$\begin{aligned}
Q_v &= A \left\{ 0.33 \frac{D}{t_r} s_{uli} + (N_c - 1) s_{uli} \right\} \\
&\quad + \gamma'_1 (A H_{cav} + V_t) \\
&\geq N_c s_{uli} A + \gamma'_1 (A H_{cav} + V_t) \text{ for } d \\
&> H_{cav}
\end{aligned} \quad (34)$$

The values of N_c should be picked from Eq. 4 using actual penetration depth of the spudcan base, i.e., $d/D = d/D$. For soft layer with a non-uniform undrained shear strength, an average value over a depth of $D/2$ can be used. However, averaging should be restricted within the soft clay layer; otherwise near the first–second layer interface, a significantly higher shear strength would be picked. Clearly, Eqs. 33 and 34 are not a function of the thickness and properties of the underlying strong layer. This is a limitation of this approach.

Merifield and Nguyen method: Recently Merifield and Nguyen (2006) and Meyer et al. (2015) carried out small strain finite element analyses on a perfectly rough-based circular surface ($d/D = 0$) footing in soft-over-stiff clay. Merifield and Nguyen (2006) presented the values of modified bearing capacity factor both numerically in tables and graphically in figures. Best fit through Merifield and Nguyen's (2006) data provides

$$\begin{aligned}
N &= 0.009 \left(\frac{D}{t_r} \right)^2 - 0.018 \frac{D}{t_r} \\
&\quad + N_{cs} \text{ for } s_{ubi}/s_{uti} \\
&= 1.25
\end{aligned} \quad (35a)$$

$$\begin{aligned}
N &= 0.033 \left(\frac{D}{t_r} \right)^2 - 0.046 \frac{D}{t_r} \\
&\quad + N_{cs} \text{ for } s_{ubi}/s_{uti} \\
&= 2.0
\end{aligned} \quad (35b)$$

$$\begin{aligned}
N &= 0.036 \left(\frac{D}{t_r} \right)^2 - 0.061 \frac{D}{t_r} \\
&\quad + N_{cs} \text{ for } s_{ubi}/s_{uti} \\
&= 2.5
\end{aligned} \quad (35c)$$

where $N_{cs} = 6.05$. For an embedded footing ($d/D > 0$), Eq. 35 can be extended using N_c instead of N_{cs} .

Meyerhof and Hanna method: The above discussion is for soft-over-stiff clay or a rigid layer. In a thin weak-over-strong layer deposit of any soils, Meyerhof (1974) and Meyerhof and Hanna (1978) suggested that the bearing capacity of a flat-based circular footing can be calculated according to

$$q_u = q_{ut} + (q_{ub} - q_{ut}) \left(1 - \frac{t_r/D}{H_f/D} \right) \quad (36)$$

where $q_{u,t}$ is the bearing capacity of the footing at the penetration depth in the top layer, $q_{u,b}$ is the bearing capacity of the bottom layer at the interface, and $H_f = 1$ for circular footing regardless of soil (i.e., either sand or clay).

CLAROM method: CLAROM (1993) somewhat blended the methods proposed by Meyerhof (1974) and Meyerhof and Hanna (1978) and Brown and Meyerhof (1969) and accounted for the effect of spudcan bottom profile as

$$q_u = q_{ut} + (q_{ub} - q_{ut}) \left(\frac{A_b}{A} \right) + \gamma'_t \frac{V}{A} \quad (37)$$

where A_b is the plan area of the spudcan bottom profile embedded in the bottom layer and V is the volume of the spudcan embedded in soil. $A_b = 0$ if the spudcan does not penetrate into the bottom layer.

For soft-over-stiff clay,

$$q_{ut} = N_{mc} \left(1 + 0.2 \frac{d}{D} \right) \bar{s}_{uti} \quad (38a)$$

$$q_{ub} = N_{cs} \left(1 + 0.2 \frac{t}{D} \right) \bar{s}_{ubi} \quad (38b)$$

where N_{mc} should be taken from Fig. 10 (Brown and Meyerhof 1969) using $\bar{s}_{ubi}/\bar{s}_{uti}$ instead of s_{ubi}/s_{uti} , $N_{cs} = 6.05$, $\bar{s}_{uti}$ is the average undrained shear strength of soft clay over thickness t_r , and $\bar{s}_{ubi}$ is the average undrained shear strength of stiff clay over thickness of $D_b/2$ (D_b is the spudcan diameter embedded in the bottom layer) under the expression of q_{ub} and over the thickness of $D/2$ under the interface for calculating $\bar{s}_{ubi}/\bar{s}_{uti}$ for picking N_{mc} from Fig. 10. This average is necessary to take into account the strength increasing with depth.

Installation of Spudcans,**Fig. 10** Modified bearing capacity factors. (After Brown and Meyerhof 1969)

For the bottom sand layer,

$$q_{ub} = 0.3\gamma'_t DN_\gamma + \sigma'_v N_q \quad (39)$$

where σ'_v is the effective overburden pressure at the interface level. For picking N_{mc} from Fig. 10, $\bar{s}_{ubi}/\bar{s}_{uti}$ should be calculated, and for which an equivalent $\bar{s}_{ubi}$ should be calculated from the expression below:

$$0.3\gamma'_t DN_\gamma = 6\bar{s}_{ubi} \quad (40)$$

In terms of limiting squeezing depth, h_{sq} (the depth range from where the spudcan starts to sense the underlying strong layer and consequently the resistance profile deviates from that without the influence of the underlying layer) solving Eq. 37, ISO suggests

$$\left(5.05 + 1.2 \frac{d}{D} + 0.33 \frac{D}{t_r}\right) s_{uti} + p'_o \geq N_c s_{uti} + p'_o \quad (41a)$$

$$\begin{aligned} & \left(5.05 + 1.2 \frac{d}{D} + 0.33 \frac{D}{t_r}\right) s_{uti} + p'_o \\ & \geq \left(6.05 + 1.2 \frac{d}{D}\right) s_{uti} + p'_o \end{aligned} \quad (41b)$$

$$\frac{t_r}{D} \leq 0.33 \quad (41c)$$

Spudcan Installation in Multilayer Soils

Cavity Depth

Investigation in multilayer soils for developing design chart for limiting cavity depth is sparse. In absence of specific expression, for multilayer clay sediments, the limiting cavity depth can be assessed using

$$\frac{H_{cav}}{D} = \left(\frac{s_{uHi}}{\gamma'D}\right)^{0.55} - \frac{1}{4} \frac{s_{uHi}}{\gamma'D} \quad (42)$$

where s_{uHi} is the intact undrained shear strength at the backflow depth, H_{cav} . Some iteration is

needed to establish H_{cav} and the resulting value of S_{uHi} .

For multilayer soil with a surface sand layer, the volume of the soil above the spudcan, V_{soil} , can be calculated in a manner similar to single-layer sands or sand over clay, as discussed previously.

Design Methods

For assessing spudcan penetration in multilayer soils, three methods will be discussed including (a) the bottom-up ISO approach and (b) the top-down approaches (Zheng et al. 2015, 2017, 2018).

Bottom-up ISO approach: The bottom-up design approach can be used combining the squeezing (for weak-over-strong layering) and punch-through (for the reverse) criteria for two-layer systems discussed previously. Firstly the bearing capacity of a spudcan at the top of the lowest two layers is computed. These two layers are then treated as one (lower) layer in a subsequent two-layer system analysis involving the immediate upper layer. The equivalent undrained shear strength at the surface of a layer is updated after the completion of assessment of penetration resistance profile of that layer (based on the calculated penetration resistance at the surface of that layer).

Top-down approaches (Zheng et al. 2015, 2017, 2018): Recently, top-down approaches have been proposed by Zheng et al. (2015, 2017, 2018) accounting for the effect of the evolution of a soil plug at the base of the spudcan, its accumulation or diminishing, and corresponding effect on the penetration resistance.

Mitigation of Punch-Through and Spudcan-Footprint Interactions

For the jack-up industry, two major concerns related to geotechnical/structural failures during installation and preloading process include (a) spudcan punch-through in layered soils (53%) and (b) spudcan lateral sliding interacting

with an existing footprint from a previous installation (15%) (Jack et al. 2013).

Spudcan Punch-Through

Punch-through incidents occur in stratified soil conditions with a surface or interbedded strong (sand or stiff clay/silt) layer overlying a weak layer. Some examples have been reported by, e.g., Young et al. (1984), Kostelnik et al. (2007), and Menzies and Lopez (2011). The consequent loss may be \$5–50 million per incident.

The risk of punch-through can be identified from the assessed spudcan load-penetration profiles using the design methods just discussed. Once the risk of punch-through failure is identified at a site, mitigation methods are required for allowing a safer installation of the rig. Conventionally, installation procedures (such as leg-by-leg preloading; InSafeJIP 2011) have been used for easing punch-through or controlling leg penetration. Recently, several other mitigation methods have been discussed: (a) application of cyclic loading in the strong soil layer to degrade the strength (Erbrich 2005), (b) perforation drilling through the strong soil layer prior to the installation of a spudcan (Maung and Ahmad 2000; Kostelnik et al. 2007; Hossain et al. 2011; InSafeJIP 2011), and (c) a foundation with a peripheral skirt on its bottom side (Teh et al. 2008; Gan et al. 2011; Hossain et al. 2014b; Li et al. 2018).

For stiff-over-soft clay deposits, Hossain et al. (2011) proposed an optimized perforation drilling pattern, as shown in Fig. 11. The experimental centrifuge results confirmed that perforation drilling is indeed effective at mitigating punch-through and severe leg run during jack-up installation in multilayered clays with interbedded stronger layers.

For sand-over-clay deposits, perforation drilling and cyclic degradation are not applicable. Hossain et al. (2014b), Lee et al. (2018), and Li et al. (2018) showed that a skirted spudcan with a skirt length $0.25D$ can effectively be used to eliminate or ease the punch-through risk. An example result is shown in Fig. 12.

Installation of Spudcans,

Fig. 11 Perforation drilling: (a) mitigated punch-through failure; (b) perforation drilling pattern. (After Hossain et al. 2011)

Spudcan-Footprint Interactions

After completing the initial operation, the legs of a jack-up rig are retracted from the seabed, leaving depressions, referred to as a crater or “footprint.” Jack-ups often return to the previous operation site for more drillings, where the footprints from previous explorations are present. Where one of the jack-up legs is located near an existing footprint slope, there is a tendency for the spudcan to slide toward the center of the footprint, inducing excessive lateral displacements and bending moments or rotations of the rig. These detrimental foundation behaviors can result in an inability to install the jack-up at the required position and even worse the occurrence of leg splay and structural damage to the whole jack-up system. The frequency of offshore incidents during installation near footprints has increased by a factor of 4 from the period 1979~1988 to the period of 1996~2005 (Osborne 2005; Jack et al. 2013).

There are several mitigation methods reported, including (a) infilling crater (Jardine et al. 2002),

(b) capping the infilled crater with gravel loading platforms, (c) stomping (Jardine et al. 2002), (d) reaming (Hartono et al. 2014), (e) perforation drilling (Hossain and Stainforth 2016), (f) successive repositioning until the legs had stabilized in the desired plan position (Brenna et al. 2006), (g) use of an identical or very similar spudcan diameter and exactly on the existing footprint (Erbrich 2005), and (h) water jetting along with the spudcan preloading (Handidjaja et al. 2009). In relation to case histories in the North Sea, Jardine et al. (2002) and Grammatikopoulou et al. (2007) examined the potential of using the former two. All the other methods require additional working leading to additional cost and time to be applied in the field.

Consequently, Jun et al. (2018a, b) have focused on tweaking spudcan shapes to ease the spudcan-footprint interactions. These studies have led to establish a novel spudcan shape with a flat base and four holes, which has been shown to be effective at easing spudcan-footprint interactions (see Fig. 13).

Intact, Damage, and Dynamic Stability of Floating Structures

Shuqing Wang and Liwei Yu
College of Engineering,
Ocean University of China, Qingdao, China

Definition

The *stability* is the capability of the *floating structure* to maintain to its upright floating position

both in still water and in waves, whether intact or damaged, and it relates to the interaction among the *center of gravity* (COG), *center of buoyancy* (COB), and *metacenter of intact* or damaged hull under various scenarios.

Scientific Fundamentals

Introduction

The stability is one of the most essential performances for offshore structures. The stability calculation, also referred as stability check, during the design, construction, and operation stage of the offshore structure is fundamental for the safety of the offshore structure and required by the administrations (e.g. Classification Society, Maritime Office). The relation of the COG, COB, and metacenter of offshore structure can be found in Fig. 1, and the nomenclature adopted in this entry is listed in Table 1.

GM and GZ

When the offshore structure inclines from its equilibrium floating position, the center of buoyancy changes from *COB* to *COB'* as shown in Fig. 2. The righting moment is generated by gravity (*G*) and buoyancy (*F*), because the *COG* and *COB'* of the offshore structure are not vertically inline as shown in Fig. 2. The righting moment provides the stability of the offshore structure to maintain its upright floating position.

The intersection point between the straight line through the COG and the original COB and the straight line through the COG and the *COB'*

after inclining is referred as the metacenter. When the angle of inclination is small, the position of metacenter doesn't change. The distance between the COG and metacenter is named as the metacentric height (GM) under small inclination. The distance between the COB and metacenter is named as the metacentric radius (BM) which is calculated as:

$$BM = \frac{I}{\nabla} \quad (1)$$

where *I* stands for the moment of inertia of the waterline area. ∇ represents the displacement of the offshore structure. Then, GM is calculated as:

$$GM = KB + BM - KG \quad (2)$$

where KB and KG are the vertical heights of COB and COG from the bottom.

The lever of the righting moment, i.e., the horizontal distance between COG and COB, is referred as the righting lever (GZ) as shown in Fig. 1. Thus the restoring moment (*M*) is represented as:

$$M = F \times GZ \quad (3)$$

The change of the righting lever (GZ) against the angle of inclination forms the righting lever curve (i.e., GZ curve) as shown in Fig. 3. The righting lever curve is calculated from the hydrostatic curves. The downflooding angle stands for the angle of inclination where the water begins to flood into hull through openings. The angle of

Intact, Damage, and Dynamic Stability of Floating Structures,
Fig. 1 COG, COB, and metacenter of offshore structure

Intact, Damage, and Dynamic Stability of Floating Structures, Table 1 The nomenclature

Symbol	Meaning	Symbol	Meaning
A	Attained subdivision index	KB, KG	Vertical height of COB and COG from the bottom
A _p	Projected area	I	Moment of inertia
BM	Metacentric radius	M	Restoring moment
C _s	Shape coefficient	P	Probability of flooding of the compartments
C _H	Height coefficient	R	Required subdivision index
COG	Center of gravity	S	Survival probability
COB	Center of buoyancy	V	The wind velocity
F	Buoyancy force	θ	Inclination angle
G	Gravity force	ρ	Air density
GM	Metacentric height	φ	Motion (the pitch angle for spar platform)
GZ	Righting lever	ζ	The damping coefficient
▽	Displacement	ω ₀ , ω	Natural frequency, exciting frequency of wave

Intact, Damage, and Dynamic Stability of Floating Structures, Fig. 2 Righting moment of the offshore structure

vanishing stability is the angle where the righting lever, i.e., righting moment, is zero. The vessel capsizes after the angle of vanishing stability and returns back to the equilibrium position before the angle of vanishing stability.

At zero angle of inclination, the gradient of the GZ curve is GM. Therefore GM should be larger than zero to guarantee a positive righting lever under small inclination. The fundamental condition for the offshore structure to maintain its upright floating position is:

$$GM > 0 \tag{4}$$

Requirements for Stability Calculation

The stability calculation checks the ability of the offshore structure to hold its upright position and

is vital for the safety of the offshore structure. In order to conduct the stability calculation, the following items are required.

General Arrangement, Compartments, and Subdivision

The general arrangement of the offshore structure is defined as the design and separation of spaces both up and under the main deck for all the required functions, machineries, and equipment as shown in Fig. 4.

In the general arrangement, the spaces are divided by transversal, longitudinal bulkheads and decks into several smaller spaces called as compartment. The major compartments include machinery and fuel compartment, cargo compartment, ballast water compartment, accommodation

Intact, Damage, and Dynamic Stability of Floating Structures, Fig. 3 Righting lever (GZ) curve

Intact, Damage, and Dynamic Stability of Floating Structures, Fig. 4 General arrangement of semisubmersible

compartment, and production equipment compartment. The detail information of each compartment including volume and position are summarized in the Table of Compartments.

The watertight transversal, longitudinal bulkheads form the watertight subdivision to prevent water from propagating to other compartments

after breaching on one compartment as shown in Fig. 5.

Loading Condition

Loading conditions are the conditions determined by the different loading of cargo, fuel, ballast, and provision in the compartment and on the deck

Intact, Damage, and Dynamic Stability of Floating Structures, Fig. 5 Watertight subdivision

Intact, Damage, and Dynamic Stability of Floating Structures, Fig. 6 Curves of the righting moment and the heeling moment (IMO 2009)

in order to meet various operational demands. Different loading conditions have different GM, GZ curves, and stability performances. Therefore, the stability calculation should be conducted on all the typical loading conditions. The loading condition table contains the load, mass, and filling rate of all the compartments. The typical loading conditions of a mobile drilling unit include towing condition, operation condition (minimum draft and maximum draft), and survival condition under storm.

Stability Curves

Stability curves are the curves required for stability calculation. The most important curves for stability calculation are the curves of the righting moment and the heeling moment as shown in Fig. 6. The right moment curve is generated from the righting lever (GZ) curve by multiplying with buoyancy force (F).

The heeling moment curve is drawn from for wind forces (F_w) calculated by the following formula (IMO 2009):

$$F_w = 0.5C_s C_H \rho V^2 A_p \quad (5)$$

where C_s is the shape coefficient depending on the shape of the structural member exposed to the wind. C_H represents the height coefficient depending on the height above sea level of the structural member exposed to wind. ρ stands for the air density. V is the wind velocity. A_p is the projected area of all exposed surfaces in either the upright or the heeled condition.

Then, the wind heeling moments are calculated by multiplying the wind force with its lever. The lever of the wind force is taken vertically from the center of pressure of all surfaces exposed to the wind to the center of lateral resistance of the underwater body of the unit.

Stability Criteria

Stability criteria are the criteria constituted by the administrations (e.g., Classification Society, Maritime Office). It sets limits for heeling angle, freeboard, GM, and stability curves to ensure the stability and safety of the offshore structure under certain wind and wave loads, whether intact or damaged. The stability criteria are designed based on the notion that the offshore structure has enough right moment to withstand the designed and extreme wind heeling moment, whether intact or damaged.

Major stability criteria for offshore structures include:

- IMO, Code for the Construction and Equipment of Mobile Offshore Drilling Units (IMO 2009)
- DNV, Offshore Standard DNV-OS-C301 Stability and Watertight Integrity (DNV 2014)
- ABS, Rules for Building and Classing Mobile Offshore Drilling Units, Part 3 Hull Construction and Equipment, 2012 (ABS 2012)
- CCS, Rules for Construction and Classification of Mobile Offshore Drilling Units, Part 3 Stability, Subdivision and Load lines, 2005 (CCS 2005).

Stability Calculation

Inclining Test

An inclining test is required for the offshore structure, when it is as near to completion as possible, to measure accurately the light ship data (weight, GM, and position of COG).

In the inclining test, certain weights P (1%–2% of the light ship displacement) are displaced by the distance L from the equilibrium position to generate a moment ($M = PL$) causing an inclination of 2–4° to the offshore structure as presented in Fig. 7. The inclination angle (θ) can be measured by a pendulum or a U-tube. Therefore the metacentric height (GM) is calculated as:

$$GM = \frac{M}{\nabla g \tan \theta} \quad (6)$$

where g is the gravitational acceleration.

Intact, Damage, and Dynamic Stability of Floating Structures, Fig. 7 Demonstration of the inclining test

Intact Stability

Intact stability is the calculation of the stability performance of the offshore structure with an intact hull. Firstly, the calculations require measuring and calculating all the centers of mass of objects on the offshore structure to identify the center of gravity (COG) and the center of buoyancy (COB) of the hull under various loading conditions. Then the intact stability calculations are divided into two categories: initial stability and stability at large angle of inclination.

Initial stability is the stability calculation at small angle of inclination (within 10–15°). It involves the calculation of COG, COB, meta-center, BM, and GM.

Stability at large angle of inclination is the stability calculation. It involves the calculation of the righting lever and moment curves.

After the intact stability calculations, the results such as weight, GM, and righting moment curve are utilized to check whether the stability criteria abovementioned are met. A typical stability criteria can be illustrated as follows (IMO 2009):

- For column-stabilized units, the area under the righting moment curve to the angle of downflooding should be not less than 30% in excess of the area under the wind heeling moment curve to the same limiting angle.
- The righting moment curve should be positive over the entire range of angles from upright to the second intercept.

Damage Stability

Damage stability is the calculation of the stability performance of the offshore structure after damage with breached compartments. It requires more complicated and heavy calculation than intact stability. Thus, special numerical software such as NAPA are typically employed to handle the heavy calculation works.

In the damage condition, one or more compartments are breached and flooded by water. Its contents are assumed to be lost and replaced by water. If contents are lighter than water (e.g., light oil), then buoyancy is lost, and the offshore structure inclines unless the compartment is on the center-line. The new floating position after flooding is achieved. Under the new floating position, the freeboard, GM, and righting moment curves are calculated (Fig. 8).

In the damage stability calculations, many damage scenarios with different compartments breached should be selected. There are two methods for damage stability calculations: deterministic damage stability and probabilistic damage stability

Deterministic damage stability is a traditional and widely used method for damage stability calculations. A deterministic extent of damage on hull is decided firstly. Then it assumed that all the compartments within this extent of damage

are breach deterministically without considering the breaching probability of these compartments. The results of deterministic stability calculations are the floating position, the freeboard, GM, and righting moment curves after breaching of one or more compartments. Then the results are utilized to check whether the deterministic stability criteria are met.

Probabilistic damage stability is a newly developed method especially for passenger vessels. The damage stability calculations are of a probabilistic nature, which are based on the breaching probability on one or more compartments and survival probability after breaching (Fig. 9).

The probability of flooding of the compartments in the hull position is calculated as P based on injury statistics (probability of opening). The survival probability S (which is the probability of survival without sinking and capsizing even in the waves) is calculated when the partition is damaged or flooded. If the survival probability S is greater than 0, it means that this ship does not capsize even if some compartment is flooded. If S is 0, it means sinking. The total survival probability A is calculated for the entire ship by integrating the product of P and S over the entire length of the ship. It is required that this value should be larger than the criteria's required value R . This survival probability A is called

Intact, Damage, and Dynamic Stability of Floating Structures, Fig. 8 Floating position of a barge after breaching on a ballast tank

Intact, Damage, and Dynamic Stability of Floating Structures, Fig. 9 Diagram for probabilistic damage stability

“attained subdivision index A,” and the regulation’s required value R is called “required subdivision index R.”

After the damage stability calculations, the results such as weight, GM, and righting moment curve are utilized to check whether the stability criteria abovementioned are met. A typical deterministic damage stability criteria can be illustrated as follows (IMO 2009):

- Columns and braces should be assumed to be flooded by damage having a vertical extent of 3 m occurring at any level between 5 m above and 3 m below the draughts specified in the operating manual.
- The angle of inclination after the damage within the extent should not be greater than 17° .
- The righting moment curve after the damage should have, from the first intercept to the lesser of the extent of weather tight integrity and the second intercept, a range of at least 7° . Within this range, the righting moment curve should reach a value of at least twice the wind heeling moment curve, both being measured at the same angle.

Dynamic Stability in Waves

The abovementioned stability calculations are all of the static nature, which consider the motions of vessels, wind, and wave loads statically. However, dynamic motions and loads can also cause stability failure event such as parametric resonance and excessive acceleration.

Parametric Resonance

Parametric resonance, as a self-resonance phenomenon, occurs with excessive inclining motion and even leads to capsizing. It can bring severe cargo loss and damage (France et al. 2003). It is caused by the time varying GM and weakening of righting moment under certain large waves. The GM and righting moment variations can be caused by either the change of the waterline area in waves (such as container ships as shown in Fig. 10) or the change of the COB in waves (such as Spar and semisubmersible platforms).

The fundamental dynamics of parametric resonance caused by the time varying of restoring characteristics can be simplified as the damping Mathieu equation:

$$\phi'' + 2\zeta\phi' + (\omega_0^2 + \epsilon \cos \omega t)\phi = 0 \quad (7)$$

Intact, Damage, and Dynamic Stability of Floating Structures,

Fig. 10 Variation on GZ curves in waves of the KCS containership (Yu et al. 2017)

where ϕ is the motion (the pitch angle for spar platform), ζ is the damping coefficient, and ω_0 and ω stand for the motion natural frequency and the exciting frequency of wave, respectively. Through the analysis on the equation, it is found that the unstable and large motion response exists when the ω/ω_0 equals to 2. Therefore, the parametric resonance occurs when the wave exciting frequency is around twice of the motion natural frequency.

Conclusion

Stability is the capability of the offshore structure to maintain its upright floating position both in still water and in waves, whether intact or damaged. It is one of the most essential performances for offshore structures and of prime importance for safety.

Stability involves a series of calculation on the COG, COB, GM, hydrostatic curves, and stability curves based on the weight distribution, general arrangement, compartment, loading conditions, etc. Traditional stability calculations include inclining tests, intact stability, damage stability, as well as check based on stability criteria. In recent years, the dynamic stability in waves such as parametric resonance and excessive acceleration are also believed to be important parts of stability.

Definition

Integrated navigation refers to the use of two or more different navigation systems to measure the same information source and extract the errors of each system from the comparative values of these measurements to correct each system. The navigation system using integrated navigation technology is called an integrated navigation system, and the navigation systems involved in the integration are called subsystems. As the inertial navigation system has the advantages of autonomy, concealment, information comprehensiveness, and broadband, it is generally used as the key subsystem of integrated navigation system. Besides the inertial navigation system, the integrated navigation system may be composed of different radio navigation systems, satellite navigation systems, acoustic positioning systems, geophysical navigation, and so on. There are many ways and depths of combination. Integrated navigation can take the advantages of each system, make up for its shortcomings, and improve positioning accuracy and data redundancy. So the integrated navigation system is more reliable and complex than a single navigation technique.

Scientific Fundamentals

Main Underwater Navigation Technology

Inertial Navigation

Inertial navigation is fully autonomous navigation that does not receive external signals or transmit signals to the outside. With three orthogonal gyros and three orthogonal accelerometers, the inertial navigation system can continuously measure the three orthogonal linear accelerations and the three orthogonal angular rates in an inertial reference frame. By navigation calculation, the information of position, altitude, and velocity is acquired. Two types of inertial navigation systems are platform and strapdown. Due to the influence of cost, energy, volume, and other factors, the strapdown inertial navigation system (SINS) is usually used for underwater vehicles. With the rapid development of the fiber-optic gyro, SINS will be more accurate, smaller in size, more reliable, cheaper, and lower in energy consumption. However, the system errors of SINS will accumulate over time, which is difficult to meet the long-distance and long-time navigation requirements. Therefore, the external navigation information from other navigation systems is necessary for SINS to correct diffuse navigation errors.

Global Navigation Satellite System (GNSS)

GNSS is a global, all-weather, high-precision, continuous and real-time navigation and position system based on radio. GNSS has the advantage of not accumulating errors with time and the obvious disadvantage of no signal underwater. In the long-distance navigation, the underwater vehicles can float onto the surface of water regularly to correct the accumulating velocity or position errors of the other navigation systems.

Acoustic Positioning System (APS)

Compared with the electromagnetic signal, the acoustic signal travels farther in water. Therefore, acoustic transmitter can be used as the beacon of underwater vehicles. At present, long-baseline (LBL), short baseline (SBL), and ultra-short baseline (USBL) are the three main APS methods. All three navigation methods need to know the ocean

condition in advance. Transducers or transducer array devices are deployed in the sea area beforehand. One or more acoustic sensors pre-installed on the underwater vehicles receive a pulse signal emitted by the transducer acoustic source. The relative position of the transducer acoustic source and underwater vehicles can be obtained by calculating the received pulse signal according to the pre-set mathematical model.

APS has no position error accumulation in underwater vehicle navigation. Accuracy of APS is related to the baseline length and the distance between the APS and the underwater vehicles. LBL positioning principle is triangulation with at least three acoustic transponders, which are deployed in the mission area. For SBL, transponders are installed at both ends of the hull of the mother ship, and triangulation is used, and the baseline is determined by the size of the mother ship. The USBL method can determine the relative position of underwater vehicles to the mother ship, and the relative distance and orientation are solved by the time of flight (TOF) and the phase difference of an acoustic pulse arriving at different receivers on the bottom of the mother ship.

Geophysical Navigation

Geophysical navigation needs to be able to establish relatively accurate underwater environmental survey maps of geophysical parameters (such as seabed depth, gravity, magnetic field, etc.) in advance. Because the seabed structure, topography, and depth are different in different sea areas, underwater vehicles can estimate their positions by measuring the geophysical parameters and comparing with the previous underwater environmental survey maps of geophysical parameters. The precondition of geophysical navigation is that the measured parameters vary sufficiently in spatial distribution.

Auxiliary Navigation Device

Doppler Velocity Log (DVL)

DVL is to calculate the relative velocity of underwater vehicles relative to the seabed or water layer by transmitting sound waves continuously to the bottom or water layer under the carrier and

according to the relationship between the returned beam and the emitted beam received by the receiver. DVL can measure the left, right, front, and back traveling velocities of underwater vehicles. DVL can work all-weather without being restricted by various environments.

Magnetic Compass (MCP)

MCP measures the direction of the geomagnetic field through the magnetic sensor and then gives the angle between the longitudinal axis of underwater vehicles and the magnetic meridian in the horizontal plane, that is, the so-called magnetic heading angle. MCP is more susceptible to external interference, so its accuracy is low. However, because of its low cost, simple structure, and high reliability, it can be used as auxiliary navigation equipment for underwater vehicles.

Work Principle

At present, the commonly used underwater navigation positioning methods include inertial navigation, terrain matching, dead reckoning, geophysical navigation, and acoustic navigation. Various single navigation methods have more or less deficiencies in accuracy, reliability, or other aspects, which cannot meet the needs of the development of underwater vehicles. In addition to improving the intrinsic performances of each single navigation device, the low-cost, high-performance integrated navigation has become another development direction of underwater navigation technology.

Most of the underwater integrated navigation system is mainly based on the inertial navigation system, supplemented by acoustic navigation, gravity matching, terrain, and geomagnetic matching system. The common working principle of an integrated navigation system is shown in Fig. 1. Each navigation system provides corresponding navigation information, which is fused by the filtering method to obtain more accurate and reliable navigation information. According to different application environments and requirements, one or more other navigation modules are chosen for integrated navigation. The general process of building integrated navigation system can be described as follows: by modeling and analyzing

Integrated Navigation,

Fig. 1 The principle of the integrated navigation system

the system structure abstractly, the state equation and measurement equation of the system is established, and the state information or state error information of the system is estimated optimally by Kalman filter, and the optimal estimation is used to correct the navigation parameter information of subsystems.

Data Fusion Technology

The essence of the integrated navigation is a multi-sensor navigation information optimization processing technology, so information fusion technology is the key technology of integrated navigation. Kalman filter method is a recursive least mean square error estimation method in the time domain, which has the characteristics of engineering application and easy realization. Kalman filter is the basic technology of information fusion estimation in an integrated navigation system. Kalman filtering method includes the direct method that directly takes the navigation parameters as the estimation objects and the indirect method that takes navigation system error as the estimation objects. The direct method reflects the dynamic process of navigation parameters, while the indirect method uses error equation, which has some approximation (Yan et al. 2013).

However, the equation obtained by the direct method is non-linear, and the order of magnitude of each navigation parameter varies greatly, which easily affects the estimation accuracy. So the indirect method is generally used in engineering.

The indirect method includes output correction and feedback correction, as shown in Fig. 2. (1) Output correction uses filter estimation as the output of the integrated system or as the output of INS to improve the accuracy of output, but it does not modify the internal error state of INS. The accuracy of filter estimation determines the accuracy of correction. Its advantage is that subsystems and filters work independently and are easy to be realized in engineering. The fault of filters will not affect the operation of the system, so it has high reliability. However, system model changes will occur during long-time operation, which will lead to the reduction of filtering accuracy. (2) Feedback correction is to feedback the filter estimation to INS and other navigation systems, whose error state will be corrected. The corrected parameters of INS and other navigation systems enter the next operation. In the feedback correction mode, the corrected attitude matrix is fed back into the system to participate in the solution, so the system error is always small, and there will

Integrated Navigation, Fig. 2 Output correction and feedback correction

be no model error, so it has higher accuracy. Engineering implementation is more complex, and filter failure will directly affect the system output, thereby reducing reliability.

There are three common data fusion structures of centralized structure, distributed structure, and hybrid structure. (1) For the centralized fusion structure, there is a total data processing center to collect the data of the whole system. The data are processed and fused by the processing center according to the corresponding algorithm. Because the original data from all sensors are processed by the fusion center, there is no loss of information, and the performance is better, and the fusion result is optimal theoretically. (2) For the distributed fusion structure, each sensor has its independent data processor. First, they perform some operations and preprocess the data by themselves. Then they directly transmit the current state estimations to the main processor of the fusion center. After fusing all local state estimations, the fusion center outputs the global estimations. Therefore, the distributed fusion is also called sensor-level fusion or autonomous fusion. (3) Hybrid fusion structure is a synthesis structure of centralized structure and distributed structure. The fusion center can obtain either original information or local state estimations.

Typical Applications

SINS/GNSS Integrated Navigation

At present, the common modes of SINS/GNSS integrated navigation are loose integration, tight

integration, and ultra-tight integration. For these three combinations, there are differences in system structure, the physical quantity used in modeling and filtering algorithm.

Loose Integration

The GNSS and SINS of the loose integration system are independent of each other in their work, and the navigation data can be solved without changing the internal structure of each subsystem. The differences of position and velocity information obtained by GNSS and SINS are transmitted to Kalman filter as the observation of the integrated navigation system. The optimal estimation of error is used to correct the SINS. If any single system is not available for a short time, the loose integration system can still provide navigation output. The loose integration system has better robustness and accuracy than those of pure SINS. However, because the noise in the system is correlative, the system error may be largen. If there are less than four stars available, the long-time unlocking of the GNSS signal will cause error divergence of the whole system. The structure of the loose integration system is shown in Fig. 3.

Tight Integration

Tight integration does not directly use the position and velocity information given by all sensors but uses the intermediate quantities of the receiver: pseudo-range and pseudo-range rate. GNSS signal receiver is needed to give the original observation information. Tight integration not only has

Integrated Navigation, Fig. 3 Structure of loose integration

Integrated Navigation, Fig. 4 Structure of tight integration

all the advantages of loose integration but also can effectively improve the dynamic performance, anti-interference performance, and filtering accuracy of the system. The system structure diagram is shown in Fig. 4. Both theory and practice prove that tightly integration navigation has higher precision. Because tightly integrated navigation uses the original information of the receiver, it can still

provide high navigation accuracy even if there are less than four stars available. Because the observation information is irrelevant, the system error convergence speed is accelerated, and the GNSS cycle slip can be effectively suppressed by INS output. However, the structure of a tight integration system is more complex, which needs to change the internal structure of the receiver to

achieve, and the computation is also large, and the real-time performance is not good.

Ultra-tight Integration

The ultra-tight integration navigation system is the most complex and the most precise integration mode. It combines INS with co-directional signal (I) and quadrature phase signal (Q) from the receiver correlator. The function of the GNSS receiver whose internal hardware structure needs to be changed is realized by software. The numerically controlled oscillator (NCO) of code ring and carrier ring are controlled by the output of navigation filter, which improves the ability of the receiver to keep signal tracking under high dynamic and interference conditions. When the receiver is out of the lock, the fast re-acquisition of the signal can also be realized by using accurate navigation parameters of the ultra-tight integration. The structure diagram is shown in Fig. 5. Because the ultra-tight integration system integrates signal tracking and data fusion, it has a complex structure, large computation, and is not easy to realize in engineering. Li et al. (2018) suggest an enhanced tightly coupled navigation approach using pseudo-range, Doppler, and carrier phase measurements, which can increase computation efficiency without iteration calculations.

INS/DVL Integrated Navigation

The INS/DVL integrated navigation mainly uses the velocity of DVL to restrain the INS accumulation error. In many applications, the DVL-aided inertial navigation system uses a depth sensor and compass as auxiliary sensors. Figure 6 shows a typical SINS/DVL integrated navigation structure. In Fig. 6, the error state Kalman filter is used to estimate the SINS navigation errors. The navigation solution and the navigation error estimates are independent of each other. The navigation error estimates are transmitted to the SINS to reset the navigation parameters. Subsequently, the corrected navigation parameters are used as recent initial conditions of the navigation equations. DVL measures the velocity of the carrier relative to the sea bottom.

Integrated Navigation Combining INS with USBL

In the SINS/USBL integrated navigation system, SINS continuously outputs the real-time information of position, attitude, and velocity acquired by navigation calculation from the data measured by three orthogonal gyros and three orthogonal accelerometers. Using the method of phase difference or phase comparison to measure the phase differences of the acoustic unit, the position of the transponder/responder in the coordinate system of the acoustic array is obtained. The relative

Integrated Navigation, Fig. 5 Structure of ultra-tight integration

Integrated Navigation, Fig. 6 SINS/DVL integrated navigation structure (Bao et al. 2019)

Integrated Navigation, Fig. 7 Schematic block diagram of SINS/USBL integrated navigation system

distance between the acoustic array and the underwater vehicles is calculated by the time of sound wave propagation in the water. USBL outputs the position information in the geographic coordinate system of underwater vehicles. Using the indirect filtering method, the differences between the position information of SINS and the position information of USBL are taken as the measurement quantities and output into the filter to obtain the optimal estimations of the states of the integrated navigation system. The navigation error of SINS is also corrected with the optimal estimations. The schematic block diagram of the SINS/USBL integrated navigation system is shown in Fig. 7.

Integrated Navigation Combining INS with Geophysical Navigation

An integrated navigation system composed of INS and geophysical navigation, which uses inertial navigation as its core, can achieve high-precision navigation by correcting the cumulative error of the INS in real time using the geophysical field within traveling range of the underwater vehicles. The principle diagram of the geophysical navigation assisted INS is shown in Fig. 8. In Fig. 8, the measured geophysical data are obtained using geophysical sensors mounted on the vehicles (see Fig. 8a). Meanwhile, according to the estimated position provided by the INS, the

Integrated Navigation,
Fig. 8 Principle diagram
of geophysical navigation
assisted inertial navigation
(Bao et al. 2019)

estimated geophysical data are achieved from an existing geophysical reference map (see Fig. 8b). Then the measured geophysical data and the estimated geophysical data are transmitted to the navigation computer. The optimal matching position of the vehicle is determined by the matching algorithm (see Fig. 8c). Through fusing the INS position and the optimal matching position, cumulative errors of the INS can be effectively corrected and the navigation performance of the INS is improved (see Fig. 8d). Geophysical navigation mainly consists of terrain matching navigation, geomagnetic matching navigation, and gravity matching navigation.

School of Engineering, Westlake University,
Hangzhou, China

Synonyms

Advanced control; Automatic control; Fuzzy control; Neural network control; Optimal control; Robust control

Definition

Intelligent Control Algorithm is a kind of control method, which could efficiently perform scheduled tasks with its own decision-making and optimization capabilities, derived from classical control theory and optimization algorithm. Underwater vehicles have become an important tool for various underwater tasks because they have endurance, stationarity, speed, and depth capability, as well as a higher factor of safety, than human divers. However, the marine environment is unstructured and hazardous, and the development of underwater vehicles will face many challenging scientific and engineering problems. In the last three decades, researchers have made great efforts to overcome these problems by using intelligent control algorithm in underwater vehicles.

Scientific Fundamentals

Underwater vehicles have been widely used in many subsea tasks, and seven critical areas in ocean system engineering are identified as follows: system for characterization of the sea bottom resources; systems for characterization of the water column resources; waste management systems; transport, power, and communication systems; reliability of ocean systems; materials in the ocean environment; and analysis and application of ocean data to develop ocean resources (Asokan and Singaperumal 2008). Very often, according to the task, the underwater vehicle is required to continuously change its operating tool and/or to pick up and release loads causing a change in behavior. That results as an inherent change in its weight, buoyancy, and hydrodynamic forces and as a consequence, a decrease in the position tracking performance. In addition, underwater vehicles have to deal with the highly dynamical underwater environment represented in the form of ocean currents and waves in shallow water (Xu et al. 2006; Xu and Xiao 2007). With this in mind, when the dynamic characteristics of the system are time dependent or the

operating conditions of the system vary, it is necessary to retune the gains or parameters to obtain the desired performance, resulting in time consumption.

Mathematical Model for Underwater Vehicle

The nonlinear model of a 6 DOF to build the mathematical model that represents the underwater vehicle dynamics two reference frames were used; one referenced to earth (called the Earth-fixed frame) and another referenced to the vehicle (called the body-fixed frame), Fig. 1 (Hernández-Alvarado et al. 2016; Fossen 2002).

Kinematic Model

The general velocity vector is represented as:

$$\mathbf{v} = [\mathbf{v}_1 \ \mathbf{v}_2]^T = [u \ v \ w \ p \ q \ r]^T \quad (1)$$

where u , v , and w are components of the linear velocity in surge, sway and heave directions, respectively, and p , q , and r are components of the angular velocity in roll, pitch, and yaw, respectively.

The position vector $\eta_1 \in \mathbb{R}^3$ and orientation vector $\eta_2 \in \mathbb{R}^3$ coordinates expressed in the Earth-fixed frame are:

$$\eta = [\eta_1 \ \eta_2]^T = [x \ y \ z \ \phi \ \theta \ \psi]^T \quad (2)$$

where x , y , and z represent the Cartesian position in the Earth-fixed frame and ϕ represents the roll angle, θ the pitch angle, and ψ the yaw angle.

The relationship between velocities in the Earth-fixed and body-fixed frames is

$$\begin{bmatrix} \dot{\eta}_1 \\ \dot{\eta}_2 \end{bmatrix} = \begin{bmatrix} J_1(\eta_2) & O_{3 \times 3} \\ O_{3 \times 3} & J_2(\eta_2) \end{bmatrix} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \end{bmatrix} \quad (3)$$

where $J_1(\eta_2) \in \mathbb{R}^{3 \times 3}$ is the rotation matrix which expresses the transformation from body-fixed to Earth-fixed frame, and $J_2(\eta_2) \in \mathbb{R}^{3 \times 3}$ is another transformation matrix that relates the angular velocity $\mathbf{v}_2 \in \mathbb{R}^3$ with the time derivative of $\eta_2 \in \mathbb{R}^3$.

Intelligent Control Algorithms in Underwater Vehicles, Fig. 1 Frame coordinates of an underwater vehicle (Hernández-Alvarado et al. 2016)

Hydrodynamic Model

Equations of motion are expressed by the following equation,

$$\begin{aligned} M\dot{v} + C(v)v + D(v)v + G(\eta) &= \tau \\ \dot{\eta} &= J(\eta)v \end{aligned} \quad (4)$$

where $v \in \mathbb{R}^n$ and $\eta \in \mathbb{R}^n$ were previously defined, $M \in \mathbb{R}^n \times \mathbb{R}^n$ denotes the inertial matrix (including the added mass), $C \in \mathbb{R}^n \times \mathbb{R}^n$ is the Coriolis matrix and centripetal forces (including the effects of added mass), $D \in \mathbb{R}^n \times \mathbb{R}^n$ refers to the damping matrix, $G \in \mathbb{R}^n \times \mathbb{R}^n$ represents the vector of gravitational forces, and $\tau \in \mathbb{R}^n$ is the input control vector.

Ocean Currents

Ocean current is generated by wind, tide, variation of densities, and re-circulation of water, among others. The detailed information about ocean currents can be obtained from the model of induced ocean currents proposed by Fossen (2002). In the mentioned work, the equations of motion are

represented in terms of relative velocity of the vehicle and the currents,

$$v_r = v - v_{CI} \quad (5)$$

where $v_{CI} = [u_C \ v_C \ w_C \ 0 \ 0 \ 0]^T$ is a non-rotational vector of the current velocity according to Eq. (3). Note that the linear velocity on the fixed frame can be transformed to linear velocity in the equation by applying the elemental rotation matrices.

Suppose the current velocity in the equation as constant or at least with a minimum variation, so that:

$$\dot{v}_{CI} = 0 \rightarrow \dot{v}_r = \dot{v}$$

Then, the relative equations of motion become:

$$M\dot{v} + C(v_r)v_r + D(v_r)v_r + G(\eta) = \tau \quad (6)$$

If the reader is interested in the derivation of the above formula, you can refer to the

literature: Marine Control Systems: Guidance (Fossen 2002).

Traditional PID Control Methods and Its Limitations

For decades, PID (Proportional + Integral + Derivative) controllers have been successfully used in academia and industry for many kinds of plants. This is thanks to its simplicity and suitable performance in linear or linearized plants, and under certain conditions, in nonlinear ones. A number of PID controller gains tuning approaches have been proposed in the literature in the last decades, most of them off-line techniques. However, in those cases wherein plants are subject to continuous parametric changes or external disturbances, online gains tuning is a desirable choice. This is the case of modular underwater vehicles where parameters (weight, buoyancy, added mass, among others) change according to the tool it is fitted with. In practice, some amount of time is dedicated to tune the PID gains of an underwater vehicle. Once the best set of gains has been achieved the underwater vehicle is ready to work. However, when the underwater vehicle changes its tool or it is subject to ocean currents, its performance deteriorates since the fixed set of gains is no longer valid for the new conditions (Hernández-Alvarado et al. 2016).

Intelligent Control Algorithms

The control issue of underwater vehicles is very challenging due to the nonlinearity, time-variance, unpredictable external disturbances, such as the environmental force generated by the sea current, and the difficulty in accurately modeling the hydrodynamic effect. The well-developed linear controllers may fail in satisfying performance requirements especially when changes in the system and environment occur during the AUV operation since it is almost impossible to manually retune the control parameters in water. Therefore, it is highly desirable to have an AUV controller capable of self-adjusting control parameters when the overall performance degrades. Various advanced control schemes for underwater robots

have been proposed in the literature as some of them are summarized below.

Fuzzy logic control: The theoretical basis of fuzzy logic control is that any real continuous function over a compact set can be approximated to any degree of accuracy by the fuzzy inference system. For control engineering applications, researchers use fuzzy logic to form a smooth approximation of a nonlinear mapping from system input space to system output space. This makes it suitable for nonlinear system control. However, determining the linguistic rules and the membership functions requires experimental data and, therefore, very time-consuming, and the rule-based structure of fuzzy logic control makes it difficult to characterize the behavior of the closed-loop system in order to determine response time and stability.

Neural network (NN) control: Neural networks attracted many researchers because they can achieve nonlinear mapping. Using NN in constructing controllers has the advantage that the dynamics of the controlled system need not be completely known (Yuh 1994). This makes NN suitable for underwater vehicle control. However, NN-based controllers have the disadvantage that no formal mathematical characterization exists for the closed-loop system behavior. The validation of the final design can only be demonstrated experimentally. There are mainly two approaches to use NN for control purpose: learning with a forward model and direct learning. In the former approach, generally, the forward model is trained by the output error or state error and then used for gain derivation (Shi et al. 2006), while in the latter approach, the state or output error is used directly to map the desired control input.

Sliding mode control (SMC): SMC restricts the system states inside a certain subspace of the whole state space and makes them asymptotically converge to their equilibrium point. It requires a raw estimation of the system parameters and an estimation of the system uncertainty for the switching surface design and variable-structure control law design. Even though SMC has been well known for its robustness to parameter variations, it has the inherent problem of chattering phenomenon.

Optimal/robust control: The principles of the optimal/robust control are calculus of variations, Pontryagin maximum principle, and Bellman dynamic programming. However, due to the difficulty of deriving an accurate model of AUV system, it is difficult to apply optimal control directly. Therefore, generally optimal control combined with system identification or robust control is used in AUV control (Zhao and Yuh 2005 and Yuh 1990).

Fuzzy Control Algorithms

Classical control theory is based on mathematical models that describe the behavior of the plant or system under consideration. Fuzzy systems are known for their capabilities to approximate any nonlinear dynamic system (Wang 1992). The main idea of fuzzy control is to build a model of a human control expert who is capable of controlling the plant without thinking in mathematical model terms.

AUV's fuzzy modeling is constructed based upon the input-output data that have been characterized from the open loop system results of the AUV's mathematical model. The input data is considered as the force generated by thruster or pump which moves the AUV in a certain direction, and the output data is considered as the

resulted linear or angular velocity of the vehicle taking into account the coupling effect of the other degree of freedom in that direction.

Figure 2 shows the configuration of a fuzzy model system, which it consists of three fuzzy logic modules that represent surge, pitch, and yaw motions. A Mamdani fuzzy controller was used in this section.

Fuzzy Modeling AUV Surge

For surge motion fuzzy model, the input for the fuzzy logic control is the force required for the thruster, X , to produce the desired motion of the AUV in forward motion corresponding to desired pose. The output of the fuzzy control is the linear velocity in x-direction, u .

Fuzzy Modeling AUV Pitch

For pitch motion fuzzy model, the input for the fuzzy logic control is the force required for the pumps (one pump for up direction and the other one for down) to produce the desired rotation of the AUV in pitch motion corresponding to desired pose. There are three outputs for this fuzzy model.

The first output of the fuzzy control is the linear velocity in x-direction, u , and this output represents the coupling effect on the forward direction, which means the effect of the pitch motion on the

Intelligent Control Algorithms in Underwater Vehicles, Fig. 2 The configuration of fuzzy modeling for the underwater vehicle (Hassanein et al. 2011)

forward motion. The second output represents the coupling effect on heave direction. The third output is the angular velocity about y-axis, q .

Fuzzy Modeling AUV Yaw

For pitch motion fuzzy mode, the input for the fuzzy logic control is the force required for the pumps (one pump for right direction and the other one for left) to produce the desired rotation of the AUV in yaw motion corresponding to desired pose. There are three outputs for this fuzzy model.

The first output of the fuzzy control is the linear velocity in x -direction, u , and this output represents the coupling effect on the forward direction, which means the effect of the yaw motion on the forward motion. The second output represents the coupling effect on sway direction. The third output is the angular velocity about z-axis, r .

Fuzzy Controller Design

The fuzzy controller is shown in Fig. 3, where the inputs to the fuzzy controller are the error and error difference. Generally the depth of AUV can be maintained by controlling the pitch and forward motion. Moving right and left of AUV can be achieved by controlling the yaw angle. The pitch and yaw angles are controlled by controlling the operating time of the pump that is responsible for moving the AUV in that direction.

For surge motion, the inputs to the fuzzy controller are “ x ” position error and its error difference. The output of the fuzzy controller is the force required by the thruster. The membership function for this controller is shown in Fig. 4. The total number of rules used for the fuzzy controller is 9.

For pitch motion, the inputs to the fuzzy controller are pitch angle error and its error difference. The output of the fuzzy controller is the time required to operate the pump to rotate the AUV in the required direction. The membership functions are the same for surge fuzzy control with different values.

For yaw motion, the inputs to the fuzzy controller are yaw angle error and its error difference. The output of the fuzzy controller is the time required to operate the pump to rotate the AUV in the required direction. The membership functions are the same for surge fuzzy control with different values (Hassanein et al. 2011).

Neural Networks (NN) Control Algorithms

PID control is widely used underwater vehicle control systems. In the absence of accurate mathematical model for underwater vehicle systems, a PID controller may be the best controller, because it is model-free, and its parameters can be adjusted easily and separately. Tuning of PID controllers depends on adjusting its parameters

Intelligent Control Algorithms in Underwater Vehicles, Fig. 3 The structure of the fuzzy control system for underwater vehicle (Hassanein et al. 2011)

Intelligent Control Algorithms in Underwater Vehicles, Fig. 4 Membership functions for the error and the derivative of the error (Hassanein et al. 2011)

(i.e., K_p , K_i , K_d), so that the performance of the system under control becomes robust and accurate according to the established performance criteria. The proposed auto-tuning algorithm is based on NN which exhibit the following characteristics:

1. Parallelism and generalization. A NN is able to produce useful outputs for inputs not provided under the learning phase.
2. Non-linearity. A NN can be linear or not allowing it to represent systems generated by non-linear guidelines.
3. Adaptability. NN is capable of re-adjusting weights and adapting to new environmental situations. This is especially useful when the system offers non-stationary data, that is, the properties involved by the system vary over time.

4. Fault tolerance. When an operational failure occurs on a local part of the network, it lightly affects the global performance.

A block diagram of the auto-tuning control for underwater vehicle with an artificial neural network (NN) is shown in Fig. 5.

In the discrete time domain, the digital PID algorithm can be expressed as follows:

$$\begin{aligned} \tau(n) = & \tau(n-1) + K_p(e(n) - e(n-1)) \\ & + K_i e(n) \\ & + K_d(e(n) - 2e(n-1) + e(n-2)) \end{aligned}$$

where $\tau(n)$ is the original control signal, $e(n) = \eta_d - \eta$ represents the position tracking error, η_d denotes the desired trajectory, K_p is the proportional gain, K_i is the integral gain, K_d is the derivative gain, and n the sample time.

Intelligent Control Algorithms in Underwater Vehicles,

Fig. 5 Block diagram of an auto-tuned PID with artificial NN control (Hernández-Alvarado et al. 2016)

Intelligent Control Algorithms in Underwater Vehicles,

Fig. 6 Block diagram of the implemented backpropagation NN (Hernández-Alvarado et al. 2016)

The algorithm used as auto-tuning is the back-propagation method, chosen for its ability to adapt to changing environments. Operation begins applying the inputs to the network (see Fig. 6), and this is propagated from the first layer to the hidden layers, up to produce output (K_p , K_i , and K_d). The output signal is compared to the desired output and an error signal is calculated for each of the outputs; this is shown in Fig. 5. The error outputs backpropagate, starting from the output layer, to all neurons in the hidden layer that contribute directly to the output; however, the hidden layer neurons receive only a fraction of the total error signal. This process repeats iteratively, layer by layer, until all neurons in the network have received an error signal describing its relative contribution to the total error.

Figure 6 presents the topology of the NN used to auto-tune the PID controller gains implemented on the ROV.

$u(n)$ and $u(n-1)$ are reference inputs (desired trajectory), $y(n)$ and $y(n-1)$ are reference outputs (real trajectory), $C(n)$ and $C(n-1)$ correspond to the control signals, w_{ji} are the weights of the hidden layer, and v_{ji} are the weights of the output layer.

The criteria used to minimize the error:

$$E(n) = \frac{1}{2} \sum_{k=1}^t (y_r(k) - y(k))^2$$

The adjustments of weighting coefficients w_{ji} and v_{ji} can be made by means of the expressions:

$$w_{ji}(n+1) = w_{ji}(n) + \left(a \frac{\partial e_y}{\partial e_u}\right) \delta_j^2 x_j$$

$$v_{ji}(n+1) = v_{ji}(n) + \left(a \frac{\partial e_y}{\partial e_u}\right) \delta_j^1 h_j$$

where a is the learning coefficient, $w_{ji}(n+1)$ is a vector of weights for the hidden layer, $v_{ji}(n+1)$ is the vector of weights of the output layer and equivalent gain $\frac{\partial e_y}{\partial e_u}$ is unknown.

Sliding Mode Control Algorithms

Because of the nonlinearity and the unpredictable operating environment of the AUVs, many design parameters must be considered during the design of AUVs control system. Indeed, the high frequency oscillating movement can seriously affect the performance of sensors, especially optical and acoustical sensors.

In brief, the main factors that make the control of AUVs difficulty are: (1) the highly nonlinear, time-varying dynamic behavior of the AUVs; (2) uncertainties in hydrodynamic coefficients; and (3) disturbances by ocean currents. To remedy these aforementioned problems and enhance the AUVs performance along with strengthen robustness, adaptability, and autonomy, it is necessary that the motion control system has the ability of learning and self-adaptation.

The AUV dynamic in (4) can be rewritten as

$$M\ddot{q} + C(\dot{q})\dot{q} + D(\dot{q})\dot{q} + G + \tau_d = \tau \quad (7)$$

Moreover, q is the configuration and τ_d represents environmental forces and/or disturbances. To make the AUV follow a prescribed desired trajectory $q_d(t)$, we define the tracking error $e(t)$ and filtered tracking error $r(t)$ by

$$e = q_d - q, \quad r = \dot{e} - \Lambda e$$

with $\Lambda > 0$ a positive definite design parameter matrices.

The AUV dynamics are expressed in terms of the filtered error as

$$M\dot{r} = -Cr + f(x) + \tau_d - \tau$$

where the unknown nonlinear function of AUV dynamic is given by

$$f(x) = M(q)(\ddot{q}_d + \Lambda \dot{e}) + C(\dot{q})(\dot{q}_d + \Lambda e) + D(\dot{q})\dot{q} + G$$

One may define $\equiv [e^T, \dot{e}^T, \ddot{q}_d^T, \ddot{q}_d^T]^T$.

A general sliding mode controller structure is based on

$$\tau = \hat{f} + K_v r - v(t)$$

with $\hat{f}$ an estimate of $f(x)$, $K_v r = K_v \dot{e} + K_v \Lambda e$ an outer PD tracking loop, an $v(t)$ an auxiliary signal as

$$v(t) = -(F(x) + \eta) \operatorname{sgn}(r)$$

where $\operatorname{sgn}(\cdot)$ is the sign function and $F(x)$ is a known function which can be computed using the boundedness property of AUV's dynamics. This term is used to maintain the robustness in the face of external forces, disturbances, and modeling error. η is a design parameter and can be selected as a small value. Employing this controller, the closed-loop error dynamics are

$$M\dot{r} = -Cr - K_v r + \tilde{f} + \tau_d + v(t)$$

where the function approximation error is defined as

$$\tilde{f} = f - \hat{f}$$

so that $\|\tilde{f}\| \leq F(x)$ and $\|\cdot\|$ is Frobenius norm.

The stability and numerical simulation of the introduced sliding mode control system can be obtained in the work of Tabar et al. (2015).

Optimal Control Algorithms

To achieve better robustness and handling coupling in the system dynamics, MIMO-based techniques such as LQR method has been reported. The literature revealed that LQR provides better performance over classical control scheme such as

PID though with higher design and implementation complexity. On the other hand, it represents the simplest model-based MIMO controller in terms of design and implementation when compared to others such as H-infinity, μ -synthesis, and nonlinear controllers. However, LQR control is a well-known optimal control method, and the optimality of the resulting compensator is a subject of appropriate design parameters' (Q and R) selection. However, one of the common challenges associated with LQR and generally with the majority of modern control techniques is their dependency on selection of appropriate design parameters. The selection is usually based on technical guess followed by several iterative tunings which are mostly based on trial and error for a given question. Considering the complexity and dimension of the underwater vehicle, this conventional trial and error design approach would be time consuming in proportionate with experience of the designer, and often limits the achievable control performance objectives which are usual conflicting. In order to overcome this, the control problem is formulated as a multi-objectives optimization task, and a proposed multi-objectives differential Evolution algorithm is applied to achieve an optimal/suboptimal compromise between the performance objectives (Alvis et al. 2007; Castillo-Effen et al. 2007; Tijani 2012).

Optimization Problem Formulation

The optimization problem is to determine the set of decision vectors Φ , which in this context is the weighting matrices Q and R 's parameters: Φ

$$\Phi := [\Phi_1 \quad \dots \quad \Phi_{n+m}]$$

that minimizes the cost function:

$$\hat{J} = \int_0^{\infty} (\hat{x}^T Q \hat{x} + \delta^T R \delta)$$

And set of performance objectives of size Ω :

$$\min f_i(\Phi), \quad i = 1, 2, \dots, \Omega$$

subject to $Q \geq 0$ and $R \geq 0$ with $0 < \Phi_j < H_j$ where H_j is the upper bound on the decision parameter Φ_j .

The problem is casted as nonconstraint optimization problem, meanwhile, depends on design goal and application requirements; it is possible to introduce additional constraints such as frequency response parameters or actuator limitation. Figure 7 shows the proposed design method.

As shown in the Fig. 1, the performance objective function is given by the response of the full-state feedback system formed for a given decision parameter set. In this study, five control objective functions are defined for the pitch angle tracking control as follows:

$$f_i(\Phi) := \left[t_s^\theta, OS^\theta, \max t_s^{(u,w,q)}, \max \beta^{(u,w,q)}, \max \delta \right]$$

where t_s^θ and OS^θ are the settling time and percentage overshoot of the pitch angle θ , respectively, $\max \beta^{(u,w,q)}$ is the maximum off-axis (other states, $\{u, v, w\}$) settling time, $\max \beta^{(u,w,q)}$ is the maximum peak of the off-axis response, and $\max \delta$ is the maximum control signal expended.

Application to the UUV System

In tracking and regulation control problem as shown in the Fig. 7, the system states are first augmented with two extra integral states vector to improve the tracking performance. The new state vector $\bar{x}_i$ is given as:

$$\bar{x}_i := \left[u, q, w, \theta, \int_0^{\infty} \theta dt \right]$$

The augmented state space model is then expressed as:

$$\dot{\bar{x}}_i := A_i \bar{x}_i + B_i \delta$$

and the control law becomes:

Intelligent Control Algorithms in Underwater Vehicles, Fig. 7 Block diagram of the proposed MODE-Based LQR controller synthesis (Tijani and Budiyo 2016)

$$\bar{\delta}_i = -K\bar{x}_i$$

As indicated in Fig. 7, the design procedure involves placing the MODE in the LQR conventional design loop for optimal tuning of the Q and R matrices, and can be summarized step-wise as follows:

- Step 1:** Specify the optimization parameters: population size, NP , decision vector size, Z , DE cross-over constant, CR , and generation size, GEN .
- Step 2:** Specify the dimension of the Q and R matrices and initialize population P of size NP for the Q and R matrices' parameters.
- Step 3:** Test for the positive definiteness of the initialized matrices, and remove any unfit parameters set(s); repeat step 2 to complete the size of population.
- Step 4:** Compute the objective function and extract the objectives vector for the population.
- Step 5:** Start the optimization process: while the stopping criteria are untrue, e.g., repeat steps 6 to 9 else go to step 10 GEN k while.
- Step 6:** Generate new child vector from randomly selected three vectors from the old population using the DE operation of mutation and cross-over processes. Test the positive definiteness of the child vector and compute its objective function.

Step 7: Compare the child vector with the parent vector for Pareto dominance. That is, determined if the child vector dominates the parent vector. If not, repeat step 6 to 7, else proceed to step 8.

Step 8: Update the new population with the dominant child vector.

Step 9: Compute the stopping criteria and update the generation count: $k = k + 1$.

Step 10: Stop the optimization and report the Pareto-dominance candidates.

The numerical simulation of the introduced optimal control system can be obtained in the work of Tijani and Budiyo (2016).

Key Applications

In the work of Hernández-Alvarado et al. (2016), the intelligent control was implemented on an underactuated mini-ROV. This vehicle is a ROV developed in CIDESI named Nu'ukul Ja (which in the Mayan language means "water instrument"). Its dimensions are: 50 cm long, 30 cm wide, and 30 cm height; as shown in Fig. 8. It has a cylindrical pressure chamber of 15 cm diameter where the major part of the electronic architecture is placed. The total weight of the ROV is 10 kg. According to the experimental environment, it was placed in a pool of 2.5 m where both PID

Intelligent Control Algorithms in Underwater Vehicles, Fig. 8 Underactuated mini-ROV under water (Hernández-Alvarado et al. 2016)

controllers (auto-tuned and conventional) were implemented.

The gains of the conventional PID control were obtained by means of the NN. The ROV was requested to get the set point of 1 m depth by using the Auto-tuned PID controller. Once the ROV reached the stability and the PID gains, computed by the NN, became stationary, these gains were programmed into the conventional PID as K_p , K_d , and K_i . This way the conventional PID gains were tuned. It is important to remark that once the conventional PID was tuned, the gains remained constant along the experiment, even when the disturbances took place, unlike the auto-tuned PID controller wherein gains were dynamically changing to attain better performance along the experiment.

The controls were evaluated by performing a data capture of 3 m, once the ROV was placed 1 m underwater. In the first minute, nondisturbance took place. After this time, the weight was increased by 400 g as disturbance until 2 min mark. Finally, in the last minute of data capture, the weight was removed. Figure 9 shows the desired trajectory (solid line) versus the real path (dotted line) and the control signals for thrusters (Hernández-Alvarado et al. 2016).

Apparently, the control signal given by the auto-tuned PID (shown in Fig. 9), seems to be more active than the conventional PID's signal; though, the root mean square (RMS) value of each

one (the complete experiment) shows that the RMS of the conventional PID is 6.8874 whereas in the auto-tuned PID is 6.6781. The auto-tuned PID has a 3.038% of energy saving against the conventional PID.

The experimental work (Zhao and Yuh 2005) of the proposed controller was carried out on ODIN III, which is shown in Fig. 10. It is a six-DOF autonomous underwater robot developed by the Autonomous Systems Laboratory of the University of Hawaii. It is a close-framed sphere-shaped vehicle that makes its dynamics in each direction nearly identical. It has eight thrusters: four horizontal and four vertical, which make ODIN III capable of six-DOF maneuvering and also have thrust redundancy for fault tolerance purpose. It also has various navigation sensors including eight sonar sensors, a pressure sensor, and an Inertial Measurement Unit (IMU). The eight sonar sensors are used to measure the displacements in the horizontal plane, the pressure sensor is used to measure the depth of the vehicle, and the IMU is used to measure the angular displacements. A Kalman filter is used to suppress the sensor noise and to estimate the translational and angular velocities. All the tests were done in the diving pool of Kahanamoku Pool at the University of Hawaii.

The effectiveness of the control system was experimentally investigated by implementing three controllers: PID, PID plus DOB, and

Intelligent Control Algorithms in Underwater Vehicles, Fig. 9 (a) Conventional PID controller, (b) auto-tuned PID (Hernández-Alvarado et al. 2016)

Intelligent Control Algorithms in Underwater Vehicles, Fig. 10 Omni-Directional intelligent navigator (ODIN III), (a) View in water, (b) Inside view (Zhao and Yuh 2005)

ADOB on the autonomous underwater vehicle, ODINIII. Figure 11 shows tracking performance in x, y, and z.

The ADOB consists of the regressor-free adaptive control and DOB, taking advantages of DOB robustness with respect to external disturbances and modeling errors, and the regressor-free adaptive controller’s robustness with respect to uncertainties in the system model. The ADOB controller has the capability of self-tuning control gains and adapting to changes in the system and

environment while PID requires a lengthy pre-tuning process for satisfactory performance. The PID would need retuning control gains when the performance degrades due to changes in the system and environment. However, it is almost impossible to retune control gains of underwater robots until they are brought up to the surface where hydrodynamics would change again. Therefore, as shown in the experimental result (Fig. 11), the ADOB controller is promising for underwater vehicles, especially when the

Intelligent Control Algorithms in Underwater Vehicles, Fig. 11 (a) PID control with external disturbance, (b) PID plus DOB control with external disturbance, (c) ADOB control with external disturbance (Zhao and Yuh 2005)

performance degrades or fails by PID type controllers (Zhao and Yuh 2005).

Internal Turret Single-Point Mooring (SPM) System

Yougang Tang

Definition

Internal turret single-point mooring system is a type of single-point mooring device and belongs to the turret type single-point mooring device. This type of single-point mooring is moored to the seabed through uniform or grouped anchor chains on a turret inside the hull. The FPSO hull rotates 360° around the internal turret under wind, wave, and flow environmental loads. It has a “weathervane effect,” which makes the hull adjust to the direction with smallest load. Because the SPM pontoon and turret are installed inside the hull, it is called the internal turret SPM system. The crude oil enters the oil storage tank through a subsea pipeline into a rotary sealed joint in the internal turret.

Development History

The world’s first SPM pontoon was designed by IMODCO in the United States in 1959 and put into production in the port of Detio (Yifeng 2012), Sweden. It is used as a deep water transport dock. The pontoon is connected to the sea floor by

Internal Turret Single-Point Mooring (SPM) System, Fig. 1 The world's first SPM pontoon (Yifeng 2012)

mooring lines, and the oil tanker is connected to the SPM device by steel cables (Fig. 1).

In the early 1980s, SBM Company first proposed a turret concept based on the principle of “weathervane effect” (Yifeng 2012). In 1985, an external turret was installed on the bow of a 140,000-ton floating storage tanker, which makes the concept formally applied to reality (Yifeng 2012). The advantage of the outer turret SPM is that the tanker’s weathervane effect is significant, which makes the rotation to the position with the smallest environmental load become easy, and does not occupy the hull storage space, so the oil tanker has high oil storage efficiency; the shortcoming is that the bow movement is the most responsive, especially in deep water mooring, and the riser and turret of the outer turret device are all within the range of wave slamming, which easily causes damage of the riser and the turret. Therefore, the outer turret SPM is only suitable for medium-deep waters with better marine environment.

In the early 1990s, the internal turret SPM system was proposed, in order to overcome the shortage of out turret SPM and meet the development demand of deep water oil and gas fields which are over 100m. (Zhigang and Yanping 2006), the internal turret SPM system was proposed. The early internal turret SPM system² is generally the permanent type. In order to adapt the FPSO mooring demand under the harsh sea

conditions, the development trend is the internal turret SPM system of detachable type.

Operational Principle and Component

The Internal Turret SPM System of Permanent Type

The early internal turret mooring system was not detachable. Generally the SPM is designed under the sea condition once in 100 years, to provide sufficient weathervane effect and mooring force under severe sea conditions and ensure the FPSO has mooring and transmission capabilities under most sea conditions. Some internal turret mooring systems of permanent type are equipped with locking devices that are tightened as necessary to limit the sudden movements of the hull.

The internal turret mooring system installed in the Marlim Leste field in Camps Bay (Zhigang and Yanping 2006), Brazil, in 2007 would be the world’s largest internal turret mooring system of permanent type. It can accommodate up to 75 hoses and is moored with 8 mooring legs in combination of polyester ropes and anchor chains.

The Internal Turret SPM System of Detachable Type

The detachable type is the development trend of SPM system. The detachable internal turret mooring system can be quickly disengaged and return

according to the working sea conditions, and can be quickly released under extreme sea conditions to avoid dangerous sea conditions that may cause personal injury and damage to floating structures. It is more suitable for offshore oil fields in harsh environments and complex sea conditions. The detachable internal turret mooring system is mostly in the form of internal turret pontoon. This single-point mooring system can be installed at sea at an early stage, which shortens the time for FPSO return operations. In recent years, the detachable internal turret SPM system is gradually designed under the conditions that FPSO is not released under the sea conditions of 100 years, making the mooring system to have the function that does not have to be released when faced with typhoon, further ensuring the personal and platform's safety and normal production. Common detachable internal turret mooring system includes: pontoon turret mooring system, submerged turret handling system, and submerged turret production system (Shan et al. 2008).

The internal turret mooring system consists of a pontoon and an internal turret which is inside the bow and connected by structural connectors. The pontoon can provide sufficient buoyancy to

withstand the weight of the mooring legs and risers. The pontoon turret mooring system is capable of repairing critical components such as manifolds under severe sea conditions. The installation of turret can be carried out in dock, reducing the amount of on-site installation work at sea. The submerged turret handling system consists of an underwater buoy and a complete turret system. The inside of the conical buoy moored to the sea floor is a turntable that connects the mooring chain and the riser system. The outer structure of the pontoon can be rotated around the turret with the hull. The submerged turret handling system can be released in any climatic conditions, and it also has a function of simple quick release and return for high safety. The submerged turret production system is a production of a submerged turret handling system and mooring technology combined with a multifunction rotary joint. It is a new generation of internal turret SPM system that integrates mooring system, turret device, and rotary joint. Figure 2 shows the detachable internal turret SPM system (<http://image.baidu.com/search/index?tn=baiduimage&ps=1&ct=201326592&lm=-1&cl=2&nc=1&ie=utf-8&word=FPSO>; Zhao 2009).

The submerged internal turret SPM mainly includes: the slip ring stack, the pontoon, the

Internal Turret Single-Point Mooring (SPM) System, Fig. 2

The internal turret SPM system of detachable type (Shan et al. 2008)

locking device, the mooring system, and so on. The details are as follows:

(1) The Slip Ring Stack

The slip ring stack, also known as the rotary joint assembly, is one of the key equipments for the mooring system. It consists of a well-flow rotary joint, an electric rotary joint (electric slip ring), a common rotary joint (common slip ring), and a supporting hydraulic control system. The rotary joint assembly is composed as shown in Figs. 3 and 4.

1. The well-flow rotary joint: The inlet end is connected to the underwater flexible hose, and the outlet end is connected to the FPSO production processing module inlet line to form a crude oil output passage. A hydraulic oil seal system is arranged on the well-flow rotary joint to ensure normal operation without leakage.
2. The electric rotary joint: Power is supplied to the platform through the electric rotary joint

and power cables for use on equipment and facilities.

3. The hydraulic rotary joint: The hydraulic rotary joint provides hydraulic power to control the emergency shutoff valve.
4. The emergency shutoff valve: It is used to shut off the oil passage in an emergency state.

(2) The Pontoon

The pontoon is conical, and its schematic diagram is shown in Fig. 5. The upper part of the pontoon is provided with a bearing assembly, and the lower part is connected to the mooring line through the lifting-eye to transmit the mooring tension. The upper part is fixed to the FPSO by a special hydraulic locking device. The FPSO rotates or drifts around the mooring center under the action of environmental loads such as wind, wave, and current through the bearing assembly on the pontoon.

(3) The Locking Device

The locking device is located in the single-point compartment, clamping and locking the pontoon, so that the FPSO is integrated with the SPM to achieve safe production. The locking device is the most critical device of a SPM system. In actual production operations, the locking device must maintain sufficient preload.

(4) The Mooring System

Most of the mooring systems adopt asymmetrical arrangement of 3×3 and 3×4 . This mooring arrangement has better adaptability to sea areas with bad conditions. In the design of the mooring system, the weighting block is generally added to the mooring line which section is laid on the seabed in order to increase the recovery stiffness and improve the resilience of the mooring system. According to this design, the length of anchor chain laid on the seabed could be reduced and the construction and installation could be more facilitated.

Application

The internal turret SPM is widely used, and most of the FPSOs worldwide use the internal turret SPM. The internal turret SPM device is located in the bow opening of the hull. The advantage is that the diameter of the turret can be designed to be large, which can provide sufficient space for the arrangement of equipment and manifolds. In addition, the turret is located inside the hull, which reduces the environment loads and effectively protects the SPM structure. The disadvantage is that the turret is installed inside the hull, affecting the arrangement of hull structures and the strength, as well as reducing the effective storage capacity (<http://image.baidu.com/search/index?>

[tn=baiduimage&ps=1&ct=201326592&lm=1&cl=2&nc=1&ie=utf-8&word=FPSO](http://image.baidu.com/search/index?tn=baiduimage&ps=1&ct=201326592&lm=1&cl=2&nc=1&ie=utf-8&word=FPSO)). In addition, the effect of the weathervane of mooring tanker is restricted by the turret. When the wind wave is large, the azimuth speed at which the tanker turns to the least force direction is slow. The internal turret SPM system is suitable in moderate sea conditions or in harsh conditions of deep sea operations.

At present, the world's largest internal turret single-point mooring device is built by Dubai DryDocks World (Zhao 2009; Shengfa 2012). This SPM unit is 100 m high, weighs 4300 tons, and is connected to the sea floor by 16 mooring lines. This mooring system positions the 600,000-ton Prelude FLNG in a gas field of approximately

CAD (Computer-aided design); CAM (Computer-aided manufacturing); CIMS (Computer integrated manufacture system); CNC (Computer numerical control); NC (Numerical control cutting)

Definition

Shipbuilding technology is generally divided into hull construction process, outfitting process, and painting process.

The hull construction process is the process of manufacturing hull components, then assembling and welding them into intermediate products (blocks) and then hoisting them to the berth for assembly into the hull. Its operations generally include ship hull lofting, ship hull marking, hull processing, hull assembly, berth assembly, and ship launching.

The shipbuilding industry generally refers to the mechanical and electrical installations, operating equipment, living facilities, various attachments, and cabin decorations other than the main hull and superstructure, collectively referred to as outfitting projects. It uses not only steel, but also nonferrous metals such as aluminum and copper and their alloys, and a wide range of nonmetallic materials such as wood, engineering plastics, cement, ceramics, rubber, and glass. Outfitting operations involve as many as dozens of work types such as assemblers, welders, carpenters, copper workers, fitters, and electricians. Therefore, ship outfitting can be divided into mechanical outfitting, electrical outfitting, piping outfitting, hull iron outfitting, and woodwork

according to the professional content; if according to the stage of outfitting work, it can be divided into outfitting parts manufacturing (purchasing), outfitting palletizing, block outfitting, block outfitting, and interior outfitting, etc.; according to the regional outfitting method, it can be divided into engine room outfitting, deck outfitting, cabin outfitting, and electrical outfitting.

The painting operation is to remove rust and apply various paintings on the inner and outer surfaces of the hull and the outfitting parts according to the technical requirements to separate the metal surface from the corrosive medium and achieve the purpose of anti-corrosion treatment. It generally includes manufacturing-level production operation systems such as steel pretreatment, block painting, block painting, berth painting, and dock painting.

The modern shipbuilding method is based on the region, so that the three different types of hull construction, outfitting, and painting are coordinated and organically combined to form an integrated construction technology of hull, outfitting, and painting, that is, the regional shipbuilding method, and to establish the production process flow shipbuilding.

Introduction

The Content and Process Flow of Shipbuilding Technology

Hull Lofting

Lofting is the first process in the shipbuilding production process. Although the workload is very small compared with the entire shipbuilding, it is a very complicated and precise work, otherwise it will directly affect the quality of subsequent processes and even the final product.

Manual lofting started in the mid-1940s. The main work contents are: hull line smoothing, drawing frame line drawing, hull component expansion, drawing construction drawing and making prototypes and sample boxes for construction, and determining additional processing and assembly allowance. Full-scale lofting is performed at the lofting table at a ratio of 1:1,

while proportional lofting is performed at a certain reduced proportion on the lofting table. These two methods are traditional lofting methods which are manual operations, labor intensive, and poor accuracy. In addition, a large area of prototypes and a large amount of materials are needed to manufacture prototypes and prototype boxes. The methods are high cost and low efficiency, which is not conducive to the development of shipbuilding in the direction of mechanization and automation.

With the development of electronic computer technology and shipbuilding technology, lofting has developed from manual lofting to mathematical lofting. It is now possible to implement computer smoothing and lofting of the whole ship's line type and structure. It can also modify the line type and structural arrangement by man-machine dialogue to realize graphic display and automatic drawing and can automatically store the obtained data in the database for the next process such as numerical control drawing, numerical control marking, numerical control cutting, thus fundamentally eliminating manual lofting (Liu et al. 2011).

Hull Marking

Marking is the subsequent process of lofting. It is to copy the shape of the hull components after lofting to the steel plate or block steel according to the sketch, sample bar, template, sample box, sample diagram or projection diagram, CNC paper tape, etc., and mark the processing and assembly symbols, construction information for use in subsequent processes (Huang 2013).

At present, most shipyards have generally adopted CNC marking. In addition, the marking device attached to the CNC cutting machine has become commonplace. The most commonly used is to install a marking mechanism or a line drawing nozzle on the CNC cutting machine, which can simultaneously mark material at the same time of cutting. Moreover, nesting also belongs to the category of marking materials (Liu et al. 2011). At present, it is generally used for interactive and automatic graphics nesting with the help of large computers.

Hull Steel Processing

The hull steel processing is to process the pre-treated steel into the specifications and shapes required by the design with machinery and tools after marking. Generally speaking, the processing of ship hull steel can be divided into two categories: cold processing and hot processing according to the processing characteristics: it can be divided into edge processing (including planning, cutting, shearing, blanking, etc.) and forming processing (including rolling, pressing, bending, orthopedics, etc.) according to the shape of the component (Li et al. 2006).

Steel Pretreatment The surface of steel generally has defects such as oxide scale, rust, local unevenness, warping, or distortion, and it is necessary to perform operations such as leveling, rust removal, applying protective primer, and drying on the steel. These operations are collectively referred to as steel pretreatment.

Steel Cutting In modern shipyards, the cutting of ship steel plates has shifted from manual cutting and photoelectric tracking cutting to CNC cutting. In addition to adopting new methods, the development of cutting technology has also turned to automation and even unmanned development through numerical control, computers, and robots. In terms of cutting technology, there are mechanical cutting, gas flame cutting, plasma cutting, laser cutting, and water jet cutting.

Edge Processing of Hull Components The edge processing of hull components generally includes three processing operations: firstly, mechanical shearing or chemical or physical cutting method is used to cut the hull components from the raw materials according to the construction information; secondly, according to the technical requirements of welding and assembly welding, groove processing is carried out on the components; and thirdly, according to the design requirements, the free edges and manholes of some components are polished with grinding wheels, thus obtaining hull components meeting different technical requirements (Ji 2005).

Forming and Processing of Hull Components

After edge processing of hull components, for some components with spatial shapes such as bending, angle folding or edge folding, bending processing methods should be used to bend or bend them into the required spatial shapes. The forming process of hull components is to process the parts (flat panels, profiles, etc.) after edge processing into the actual shapes required by the components. Generally speaking, the bending operation accounts for about 10% ~ 18% of the hull steel processing work, while the bending restriction of profiles accounts for 9% ~ 16%.

① Sheet forming processing: marine sheet metal has complex line types, and its processing has always been the most difficult work in shipbuilding industry. Usually, conventional cold working equipment (plate bending machine, hydraulic press, etc.) is used for plate parts with general single curvature or small curvature, while for complex linear outer plates (hyperbolic plates), it still needs to be solved by hot working or water-fire plate bending process, etc. Mechanization and automation technology of plate processing has always been an important research content in hull construction.

② Profile forming and processing: generally, shipyards mostly use hydraulic profile bending machines to bend and form profiles. In recent years, CNC frame control cold bending technology and equipment have been continuously developed and are developing towards artificial intelligence and microcomputer control.

Hull Assembly

Hull assembly is the process of assembling qualified hull parts into sub-assembling, block, mega block and up to the entire hull. Due to the use of mathematical lofting and various numerical control processing technologies and equipment, the processing accuracy of hull components has been continuously improved, which has made the mechanization and automation of the hull assembly operation continuously improved. According to statistics, assembly and welding account for 12–18% of the total labor in ship construction. Therefore, improving the mechanization and

automation of assembly and welding operations can not only reduce labor intensity, but also effectively shorten the cycle and improve quality (Suwasono et al. 2011).

Hull assembly generally includes component assembly (such as various welded T-beams, frame frames, stern posts, and rudders), block assembly (such as flat section, curved section, semi-dimensional unit, three-dimensional unit, and mega block), and berth assembly (blocks assembly, large three-dimensional blocks, and blocks into the entire hull on the berth or in the dock).

Ship Launching

When the ship is built on the berth (or in the dock) to the predetermined amount of work, it needs to rely on special equipment and operation methods to move the ship into the water. This operation is called ship launching. There are many ways to launch a ship, which can be roughly divided into three types:

On the inclined slipway, the ship uses the component force generated by its own weight to overcome the friction between the slipway and the ship, so that the ship slides into the water by itself, which is called gravity launching.

Using the towing slide to cooperate with the launching vehicle (ship lift, etc.) to tow the ship into the water is called towed launching.

Water is drained into the dock to float the ship itself, and then the dock door is opened and the ship is towed out, which is called floating launch.

Ship Test

The ship test includes mooring test, tilt test, and sailing test, which are divided into two test stages.

The mooring test is a test that the ship is moored on the dock after the ship is basically completed and the shipyard obtains the consent of the ship owner and the survey agency. Its task is to test the ship's main engine, auxiliary machinery, and various equipment systems according to the design drawings and test procedures to check the ship's integrity and reliability. Then the ship is placed in a still water area and a tilt test is performed to determine the center of gravity of

the completed ship. These two tests constitute the first stage of the ship test.

The sailing test is a comprehensive assessment of a newly built ship, including two types of light-load test and full-load test. It belongs to the second stage of the ship test and is carried out by the shipyard together with the shipowner and the survey agency.

Before the test, the sea trial should be carried out at sea or in the river according to the type of ship. Before the ship sails, fuel, life-saving, daily necessities, test instruments, meters, and special test equipment should be prepared. During the sea trial, various technical indicators of the main engine, auxiliary engines, various equipment systems, and communication and navigation instruments should be measured, and various navigation performance indicators of the ship should be measured to check whether they meet the design requirements.

Delivery and Acceptance

After the ship test, the shipyard should immediately organize and implement various operations to eliminate the defects found in the test. At the same time, the ship and all equipment on board should be submitted to the shipowner for inspection one by one in accordance with the drawings, instructions, and technical documents, for example, the handover of cabins, the inventory handover of spare parts, the handover of main engines, auxiliary engines, various equipment systems, and communication and navigation equipment.

After the above work is completed, the delivery and acceptance documents can be signed, and the survey agency will issue a certificate of conformity, and the shipowner can arrange for the ship to participate in operation.

Shipbuilding Mode

Connotation of Shipbuilding Mode

Pattern is the standard form or standard style of things and the description of the basic characteristics of things. For complex shipbuilding projects, because different shipyards have different technical levels and production conditions, even if their basic shipbuilding characteristics are the

same, the specific shipbuilding methods adopted are also different. For example, it is also a shipyard that adopts the sectional construction method, but its berth assembly method and sectional manufacturing method will vary according to the conditions of the shipyard. Therefore, the shipbuilding mode does not reflect the specific shipbuilding method (Koenig 2001).

Shipbuilding mode is the general term of shipbuilding system and technology. It expresses the existence form and activity mode of shipbuilding industry as a whole and dynamically. Analyze the past and present of shipbuilding industry and explore its future and the shipbuilding mode have shown an orderly development.

The Orderly Development of Five Shipbuilding Modes

With the advancement of science and technology and the growth of ship demand, the shipbuilding mode is constantly developing and changing, but it is relatively stable and unchanging for a period of time.

The traditional shipbuilding industry is a labor-intensive industry. A large shipyard has tens of thousands of employees and produces tens of thousands of tons of ships per year. The world-class modern shipyard has an annual production capacity of more than one million tons of ships, and the total number of employees is only about 1000. The fundamental reason for such a disparity in production efficiency is the timely introduction of advanced manufacturing technology at that time. Before the 1950s, riveting technology was mainly used to develop the ancient wooden ship construction into modern shipbuilding with steel ship construction as the main body. In the 1960s, welding technology generally replaced riveting technology, transforming the ancient shipbuilding method oriented by "system" into "region" orientation, extending the assembly, outfitting, and painting operations originally concentrated on berths and docks to larger working surfaces of workshops and platforms. Since the 1970s, with the large scale of ships, in the construction of new shipyards and the modernization of old shipyards, the "group technology" has been introduced and studied comprehensively and deeply. Through the

similarity analysis of different types of construction processes, the classification of ship areas, operation types, and construction stages has been realized, and the shipbuilding flow water and virtual flow water production have been organized according to the concept of “intermediate products.” As a result, a large number of mechanized equipment have replaced heavy manual labor, and the original labor-intensive shipbuilding industry has undergone a qualitative change, becoming a modern “equipment-intensive” industry, and the total number of employees has been reduced by orders of magnitude. The “decentralized” specialization mechanism of social technology (organizational technology) in shipbuilding has been actually brought into play, and productivity has been significantly improved. Since the 1980s, the application of electronic computer technology in shipbuilding CAD (computer-aided design) and CAM (computer-aided manufacturing) has continued to expand and deepen, and shipbuilding precision control technology and ship engineering management technology are improving day by day, which has enabled the “integration” of shipbuilding social technology. The mechanism is fully functioning, and it is moving towards the integration of “space separation and orderly time,” namely the development of CIMS (Computer Integrated Manufacture System) of the shipbuilding industry, and then becoming an “information-intensive” industry, that is, an advanced state of modern shipbuilding mode (Podder et al. 2015).

Currently, countries with advanced shipbuilding technology in Europe, America, and Asia are developing shipbuilding technology with two different technical routes. The first is the “simulation technology” route, which uses computer technology, robotics, and artificial intelligence technology on the basis of intensive shipbuilding equipment. The second is the “innovative technology” route, through the concept of digitization, simplifying the design, manufacturing and operation of ships, characterized by precision and agility, and strive to study a new generation of shipbuilding mode.

For half a century, riveting technology, welding technology, group technology, and

information technology have promoted and dominated the development of shipbuilding mode one by one and successively formed the ship’s “integrated manufacturing mode,” “segmented manufacturing mode,” and “separated manufacturing mode,” and “integrated manufacturing mode.” This deductive process is an innovative process in which technology and economy are closely combined. The formation of each mode is due to the introduction of a new leading technology and the establishment of a new production function, which introduces a new combination of production factors and production conditions into the production system. Its development, like the whole manufacturing industry, is based on “technology as the center.” The development of shipbuilding industry is closely related to the improvement of the scientific and technological level of the whole industry. It is essentially a comprehensive effect produced by the organic combination of soft technology research and development and hard technology equipment and facilities investment. The transformation of the global shipbuilding mode fully reflects the convergence of technologies, that is, it does not tend to be the same with regional influence, showing the development law of shipbuilding technology (Tokola et al. 2016).

Development Trend of Shipbuilding

At present, the development trends of shipbuilding technology mainly include: low-consumption and high-efficiency ship production technology, green shipbuilding technology, digital shipbuilding technology, and intelligent shipbuilding technology.

High Production Efficiency of Shipbuilding

High production efficiency shipbuilding: giant block, large-scale unit, outfitting unit assembly line, laser or electric induction heating outer plate forming, curved surface block assembly line, robot group welding of hull structure, and efficient welding technology, etc (Xu 2005).

Low resource consumption shipbuilding: shipyard production processes without intermediate storage yard, shipbuilding activities moving forward and parallel, flange welding before bending pipe processing technology, etc.

Greening of Shipbuilding

Greening of shipbuilding is a shipbuilding technology with the highest utilization rate of production resources and the smallest impact on the environment. Therefore, the shipyard is responsible for environmental protection during shipbuilding; the pollution to the ocean must be reduced during ship operation; after the ship is scrapped, most of the materials can be reused. Therefore, greening of shipbuilding includes two aspects: “greening of ships” and “greening of shipyards.”

“Greening of ships” can be called 3R Ship: environmentally friendly design, harmless materials, efficient technology, and antipollution equipment are adopted in shipbuilding and using ships to reduce the consumption of materials and energy and the pollution to the land and sea environment. When repairing the ship, the spare parts can be conveniently classified and recycled. When the ship is decommissioned, most of the materials can be reused.

Research and development of greening of shipbuilding cases: the automation of hull processing and assembly and welding can be fully realized, and the utilization rate of steel can be improved; single-pass welding should be replaced by multiple-pass welding to reduce environmental pollution caused by welding smoke arc; non-emission steel pretreatment and coating technology should be adopted; shipbuilding sites should be sealed; and the air in the cabin should be filtered.

Digitization of Shipbuilding

The goal of digital shipbuilding: the entire shipbuilding process is accurately defined by the computer system and all shell outfitting operations and system test tasks are specified in the form of electronic process charts, as well as production resources and operating methods to perform the tasks. Then, the integrated process chart is released to all construction departments including subcontractors. For this reason, the database of the manufacturing part of the digital shipbuilding must be stored, and the historical data of the solution, the logical data of the relationship, and

the capability data of all parties must be updated in real time. Digital shipbuilding requires three-dimensional modeling of “ships” and “shipyards” in order to use the shipyard’s 3D environment to make process, operation plans, robot operations, NC (Numerical Control Cutting) simulations, and logistics simulations.

Before the production process, the operations of each cutting seam, assembly seam, and welding seam of the ship must be simulated in the computer to obtain relevant technical data and management data (Stott et al. 2018).

Intelligent Shipbuilding

With the development of shipbuilding technology, a large number of intelligent software and hardware suitable for it will surely appear.

Globalization of Shipbuilding

Global economic integration refers to the adjustment of industrial structure in the world and the flow of production factors in the global scope. Production resources are allocated beyond national borders, so a unified development trend, process, and result are formed. Its main feature is “parallel and seamless integration in different places.” “Parallel in different places” aims to maximize the assembly efficiency (using giant blocks and giant outfitting units) and minimize shipbuilding costs (ship component processing park and transnational ship production block. According to the comprehensive modularization and digitization of manufacturing, the “seamless integration” of the whole process of ship construction in terms of technology and time is realized.

Inventory of Hazardous Materials

Xifeng Gao, Enhao Wang and Wanhai Xu
State Key Laboratory of Hydraulic Engineering
Simulation and Safety, Tianjin University,
Tianjin, China

Definition

An Inventory of Hazardous Materials (IHM) is a document in which all potentially hazardous materials onboard a vessel that can pose a risk to the health and safety of people or to the environment is located, identified, and quantified.

Scientific Fundamentals

IHM is an inventory that details the type, amount, and location of hazardous materials in the constructions, systems, and equipment of a vessel. It is increasingly recognized as a means to enhance onboard safety and environmental awareness throughout the whole life until the ship is being recycled.

An IHM on board primarily concerns a limited number of hazardous materials, such as asbestos, ODS, PCBs, PFOS, and antifouling that need to be assessed. If technically feasible, heavy metals, radioactive components, and some other substances should also be assessed.

The main objectives of IHM are:

1. To gain insight into and have at hand specific information about the presence of hazardous materials on board ships
2. To safeguard the health and safety of workers and crew throughout the ship's life cycle and beyond, thus also during dismantling
3. To prevent environmental pollution in and around shipyards, docks, shipbreaking yards, and ship recycling companies

Background

Ship scrapping industry used to be virtually unregulated and even was one of the worst safety record industries, which caused massive environmental pollution. People had little awareness or acknowledgment of the appalling working conditions and environmental pollution until environmental groups brought widespread awareness of ship scrapping practices (Naruse et al. 2010).

In order to address the issues in shipbreaking, industry working groups developed the Industry Code of Practice on Ship Recycling. This guidelines subsequently fed into discussions at the International Maritime Organization (IMO), which resulted in the IMO Guidelines on Ship Recycling, adopted by member states in December 2003. These voluntary guidelines introduced the concept of a “Green Passport,” which is the predecessor of IHM, for the first time (Lloyd's Register 2014).

In 2009, the Hong Kong International Convention for the Safe and Environmentally Sound Recycling of Ships (the Hong Kong Convention, or the HKC, for short) was formally adopted at a Diplomatic Conference in Hong Kong. The HKC requires that each ship shall have on board an IHM. The Inventory is detailed in accordance with the actual conditions of each ship and shall specify at least the hazardous materials listed in

Appendices 1 and 2 of the Regulations for Safe and Environmentally Sound Recycling of Ships and the hazardous materials contained in hull structures and ship's equipment. The location and approximate number of them should be noted clearly.

The IHM consists of three parts (van Hooren 2015):

Part I: Materials contained in ship structures or equipment. Part I of the IHM shall be developed for new and existing ships.

Part II and Part III: Operationally generated wastes and stores. These parts do not need to be completed until the ship is being prepared for recycling.

Materials that shall be listed in Part I of the IHM are divided in two categories:

Table A: Comprises materials listed in Appendix 1 of the HKC. All Table A materials, if present on board, shall be included in the IHM.

Table B: Comprises materials listed in Appendix 2 of the HKC. Table B materials, if present onboard, shall be included in the IHM of new ships if above the threshold values. For existing ships Table B materials shall be listed as far as practicable.

The time window between the adoption of the HKC and its entry into force led to the appearance of a parallel convention, the EU Ship Recycling Regulation (the EU Regulation), which entered into force on 30 December 2013. The Regulation is mostly aligned with the Hong Kong Convention but differs in some aspects.

The EU Regulation requires the establishment of a list of approved ship recycling facilities (the "EU List") which meet the design, construction, and operation requirements of the EU but may be anywhere in the world (European Parliament 2013).

The requirements for an EU IHM are expected to be more onerous than for the HKC IHM, especially in terms of the accuracy and comprehensiveness. Guidance is expected to be produced by the European Commission (EC) on implementation.

It should be noted that the EU Regulation, in addition to the Hong Kong Convention requirements, does not permit the presence of the following hazardous materials: perfluorooctane sulfonic acid (PFOS) and brominated flame retardant (HBCDD).

Since the EU Regulation is at present incomplete in its requirements in so far as the permitted threshold values are concerned and is in the process of being amended, for implementation of the requirements of this Regulation, consideration should be given to the guidelines developed by the IMO to support the Hong Kong Convention.

Hazardous Materials

The Hong Kong Convention

The tables below show the category of hazardous materials and the minimum list of items for the IHM that should be listed in the Hong Kong Convention (International Maritime Organization 2009).

The EU Regulation

Hazardous materials in the EU Regulation are mostly covered by the Hong Kong Convention, but there are still some differences.

For ozone-depleting substances, except those in the Hong Kong Convention, HCFC-22 chlorodifluoromethane is prohibited in the EU Regulation. However, hydrochlorofluorocarbons (HCFCs) contained in new installations are permitted until 1 January 2020 in the Hong Kong Convention.

The EU Regulation also involves perfluorooctane sulfonic acid (PFOS) in the category of hazardous materials. Perfluorooctane sulfonic acid (PFOS) means perfluorooctane sulfonic acid and its derivatives. In accordance with Regulation (EC) No 850/2004 of the European Parliament and of the Council, new installations which contain perfluorooctane sulfonic acid (PFOS) and its derivatives shall be prohibited.

As for the list of items for the Inventory of Hazardous Materials, the EU Regulation adds brominated flame retardant (HBCDD) to the Hong Kong Convention.

Key Applications

Development of Part I of the IHM for New Ships

Part I of the IHM for new ships should be developed at the design and construction stages (Yan and Liu 2011).

Checking of Materials Listed in Table 1

During the development of the Inventory (Part I), the presence of materials listed in Table 1 should be checked and confirmed; the quantity and location of Table 1 materials should be listed in Part I of the Inventory. If such materials are used in

compliance with the Convention, they should be listed in Part I of the Inventory. Any spare parts containing materials listed in Table 1 are required to be listed in Part III of the Inventory.

Checking of Materials Listed in Table 2

If materials listed in Table 2 are present in products above the threshold values, the quantity and location of the products and the contents of the materials present in them should be listed in Part I of the Inventory. Any spare parts containing materials listed in Table 2 are required to be listed in Part III of the Inventory.

Inventory of Hazardous Materials, Table 1 Hazardous materials and control measures

Hazardous materials	Definitions	Control measures
Asbestos	Materials containing asbestos	For all ships, new installation of materials which contain asbestos shall be prohibited
Ozone-depleting substances	Ozone-depleting substances means controlled substances defined in paragraph 4 of article 1 of the Montreal Protocol on Substances that Deplete the Ozone Layer, 1987, listed in Annexes A, B, C, or E to the said Protocol in force at the time of application or interpretation of this Annex Ozone-depleting substances that may be found on board ship include but are not limited to: Halon 1211 Bromochlorodifluoromethane Halon 1301 Bromotrifluoromethane Halon 2402 1,2-Dibromo-1,1,2,2-tetrafluoroethane (also known as Halon 114B2) CFC-11 Trichlorofluoromethane CFC-12 Dichlorodifluoromethane CFC-113 1,1,2-Trichloro-1,2,2-trifluoroethane CFC-114 1,2-Dichloro-1,1,2,2-tetrafluoroethane CFC-115 Chloropentafluoroethane	New installations which contain ozone-depleting substances shall be prohibited on all ships, except that new installations containing hydrochlorofluorocarbons (HCFCs) are permitted until 1 January 2020
Polychlorinated biphenyls (PCB)	“Polychlorinated biphenyls” means aromatic compounds formed in such a manner that the hydrogen atoms on the biphenyl molecule (two benzene rings bonded together by a single carbon-carbon bond) may be replaced by up to ten chlorine atoms	For all ships, new installation of materials which contain polychlorinated biphenyls shall be prohibited
Antifouling compounds and systems	Antifouling compounds and systems regulated under Annex I to the International Convention on the Control of Harmful Antifouling Systems on Ships, 2001 (AFS Convention), in force at the time of application or interpretation of this Annex	1. No ship may apply antifouling systems containing organotin compounds as a biocide or any other antifouling system whose application or use is prohibited by the AFS Convention 2. No new ships or new installations on ships shall apply or employ antifouling compounds or systems in a manner inconsistent with the AFS Convention

Inventory of Hazardous Materials, Table 2 Minimum list of items for the IHM

Any hazardous materials listed in Table 1
Cadmium and cadmium compounds
Hexavalent chromium and hexavalent chromium compounds
Lead and lead compounds
Mercury and mercury compounds
Polybrominated biphenyl (PBBs)
Polybrominated diphenyl ethers (PBDEs)
Polychlorinated naphthalenes (more than three chlorine atoms)
Radioactive substances
Certain short-chain chlorinated paraffins (alkanes, C10–C13, chloro)

Process for Checking of Materials

The checking of materials should be based on the Material Declaration furnished by the suppliers in the shipbuilding supply chain (e.g., equipment suppliers, parts suppliers, material suppliers).

To preclude the introduction of non-compliant components into a vessel's structure or equipment after the Inventory for the vessel has been prepared, Material Declarations are also to be obtained for purchases of spare parts that would be included in the vessel's spares at delivery.

If any of the Material Declarations for spare parts contain materials listed in Tables 1 or 2 above the respective threshold values, these spare parts are to be documented in an appendix to Part I of the IHM. When these spare parts are used, Part I of the IHM is to be updated accordingly.

Development of Part I of the IHM for Existing Ships

When compiling the Part I of the IHM for existing ships, reference can be got from the IMO "Guidelines for the Development of the Inventory of Hazardous Materials" or guidelines from other classification societies.

Many of the items referred to or requested can be found in the ship's onboard documentation and plans. Machinery specifications should show details of items such as gaskets, synthetic bearings, heat insulation, oils, plastics, asbestos, and

transformer cooling media. Insulation and accommodation plans should show many of the common materials in the ship. Electrical drawings and specifications should show details of wiring and wiring coverings. The items themselves may well be labeled, for example, lighting ballasts (for PCB content) and HVAC and refrigeration systems (for refrigerant type).

The process of preparing an Inventory of Hazardous Materials is shown in Fig. 1, which is simplified from the IMO guidelines (International Maritime Organization 2011):

1. Collection of necessary information
2. Assessment of collected information
3. Preparation of visual/sampling check plan
4. Onboard visual check and sampling check
5. Preparation of Part I of the Inventory and related documentation

Collection of Necessary Information

The shipowner should identify research, request, and procure all reasonably available documentation regarding the ship. Information that will be useful includes maintenance, conversion, and repair documents; certificates, manuals, ship's plans, drawings, and technical specifications; product information data sheets (such as Material Declarations); and hazardous material inventories or recycling information from sister ships. Potential sources of information could include previous shipowners, the ship builder, historical societies, classification society records, and ship recycling facilities with experience working with similar ships.

Assessment of Collected Information

The information collected in Step 1 above should be assessed. If one or more materials listed in Table 1 are found to be present in concentrations above the specified threshold value, the products which contain these materials shall not be installed on a ship. However, if the materials are used in a product in accordance with an exemption specified by the Convention (e.g., new installations containing hydrochlorofluorocarbons (HCFCs) before 1 January 2020), the product should be listed in the Inventory. If one or more

Inventory of Hazardous Materials, Fig. 1 Flow diagram for developing Part I of the Inventory

materials listed in Table 2 are found to be present in concentrations above the specified threshold value, the products should be listed in the Inventory. The results of the assessment should be reflected in the visual/sampling check plan.

Preparation of Visual/Sampling Check Plan

While the original IMO Guidelines on Ship Recycling did not require sampling to be carried out, the Hong Kong Convention does require it, for existing ships. This new requirement is in Regulation 5.2, as follows:

Existing ships shall comply as far as practicable with paragraph 1. . . The Hazardous Materials listed in Appendix 1, at least, shall be identified when the Inventory is developed. For existing ships, a plan shall be prepared describing the visual/sampling check by which the Inventory of Hazardous Materials is developed, taking into account the guidelines developed by the Organization.

The requirement for sampling is further amplified in the IMO guidelines:

To specify the materials listed in Appendix 1 of these guidelines, a visual/sampling check plan should be prepared taking into account the collated information and any appropriate expertise.

The visual/sampling check plan is based on the following three lists:

1. List of equipment, system, and/or area for visual check. Any equipment, system, and/or area specified regarding the presence of the materials listed in Appendix 1 by document analysis should be entered in the list of equipment, system, and/or area for visual check.
2. List of equipment, system, and/or area for sampling check. Any equipment, system, and/or area which cannot be specified regarding the presence of the materials listed in Appendix 1 by document or visual analysis should be entered in the list of equipment, system, and/or area as requiring sampling check. A sampling check is the taking of samples to identify the presence or absence of hazardous material contained in the equipment, systems, and/or areas, by suitable and generally accepted methods such as laboratory analysis.

3. List of equipment, system, and/or area classed as “potentially containing hazardous materials.” Any equipment, system, and/or area which cannot be specified regarding the presence of the materials listed in Appendix 1 by document analysis may be entered in the list of equipment, system, and/or area classed as “potentially containing hazardous materials” without the sampling check. The prerequisite for this classification is a comprehensible justification as to the impossibility of conducting sampling without compromising the safety of the ship and its operational efficiency.

Visual/sampling checkpoints should be all points where:

1. The presence of materials to be considered for the Inventory (Part I) as listed in Appendix 1 is likely
2. The documentation is not specific
3. Materials of uncertain composition were used

Onboard Visual/Sampling Check

The onboard visual/sampling check should be carried out in accordance with the visual/sampling check plan. When a sampling check is carried out, samples should be taken, and the sample points should be clearly marked on the ship plan with the sample results referenced. Materials of the same kind may be sampled in a representative manner. Such materials are to be checked to ensure that they are of the same kind. The sampling check should be carried out drawing upon expert assistance.

Any uncertainty regarding the presence of hazardous materials should be clarified by a visual/sampling check. Checkpoints should be documented in the ship’s plan and may be supported by photographs.

If the equipment, system, and/or area of the ship is not accessible for a visual check or sampling check, they should be classified as “potentially containing hazardous materials.” The prerequisite for such classification should be the same prerequisite as in Step 3. Any equipment, system, and/or area classed as “potentially

containing hazardous materials” may be investigated or subject to a sampling check at the request of the shipowner during a later survey (e.g., during repair, refit, or conversion).

For example, if you have a room with many diverse items, all of which have a high likelihood of being asbestos, it may be economically more viable to declare them all as asbestos and treat them accordingly. Alternatively, if the ship has a space with a large amount of concrete in it which is highly homogeneous, has a low likelihood of containing asbestos, and would be very expensive to remove as an asbestos waste, then a practical set of tests to provide the required confidence that the material does not contain asbestos would be sensible.

Most importantly, the approach should be transparent and demonstrate the required duty of care. The first step to achieving this is to assume the worst possible hazard, to take all precautions, and then to design the sampling regime on this basis.

Shipowners can further enhance the Inventory and better discharge their liability by carrying out a limited amount of testing of known materials, in order to satisfy themselves that the available information is accurate and reliable.

Lastly, it is expected that an authorized recycling facility could be capable of checking the principal hazards itself or for the ship to have been pre-cleaned by a yard authorized for that hazard.

Each facility should have its own sampling procedures independent of anything which is in the IHM, since the Inventory is only based on “estimates” and the facility is expected to discharge its responsibility to its own workers in a sensible manner. This is essential when one considers the inaccuracies inherent in any Inventory and the lack of knowledge of what is behind, under, or around anything which may have been sampled.

The knowledge that a facility will “double check” and the fact that an owner can ask the facility to test materials he has been unable to test (due to time, access, cost, or other factors) can also impact on the economic balance of the sampling plan.

Only when the ship is being dismantled can actual, accurate checks of all material be made. Thus, sampling for the Inventory only adds confidence; it can never provide a factual record of all materials on board the ship, and it cannot do the job of checking during dismantling, which must be done by an authorized recycling facility.

Preparation of Part I of the Inventory and Related Documentation

If any equipment, system, and/or area is classed as either “containing hazardous materials” or “potentially containing hazardous materials,” their approximate quantity and location are to be listed in Part I of the Inventory. These two categories are to be indicated separately in the remarks column of IHM. The results of the onboard visual/sampling check are to be recorded on the checklist. Part I of the Inventory is to be developed with reference to the checklist. After the development of IHM, the shipowner is to determine the identification/verification number for Part I of IHM of the ship according to its own management system documents.

The information received for the Inventory, as contained in Tables 1 and 2, ought to be structured and utilized according to the following categorization for Part I of the Inventory: (1) paints and coating systems, (2) equipment and machinery, and (3) structure and hull. The following tables show the standard format (Tables 3, 4, and 5).

“Name of Equipment and Machinery” Column

Equipment and Machinery The name of each item of equipment or machinery should be entered in this column. If more than one hazardous material is present in the equipment or machinery, the row relating to that equipment or machinery should be appropriately divided such that all of the hazardous materials contained in the piece of equipment or machinery are entered. If more than one item of equipment or machinery is situated in one location, both name and quantity of the equipment or machinery should be entered in the column (American Bureau of Shipping 2016).

Inventory of Hazardous Materials, Table 3 Paints and coating systems containing materials

No.	Application of paint	Name of paint	Location	Materials (classification in Table 1)	Approximate quantity		Remarks
1	Anti-drumming compound	Primer, xx Co., xx primer #300	Hull part	Lead	35.00	kg	
2	Antifouling	xx Co., xx coat #100	Underwater part	TBT	120.00	kg	

Inventory of Hazardous Materials, Table 4 Equipment and machinery containing materials

No.	Name of equipment and machinery	Location	Materials (classification in Table 1)	Parts where used	Approximate quantity		Remarks
1	Switch board	Engine control room	Cadmium	Housing coating	0.02	kg	
			Mercury	Heat gauge	<0.01	kg	Less than 0.01 kg
2	Diesel engine, xx Co., xx #200	Engine room	Lead	Starter for blower	0.01	kg	Revised by XXX on 20 October 2008 (revoking No. 2)
3	Diesel generator (x 3)	Engine room	Lead	Ingredient of copper compounds	0.01	kg	
4	Radioactive level gauge	No. 1 cargo tank	Radioactive substances	Gauge	5 (1.8E+11)	Ci (Bq)	Radionuclides: ⁶⁰ Co

Inventory of Hazardous Materials, Table 5 Structure and hull containing materials

No.	Name of structure element	Location	Materials (classification in Table 1)	Parts where used	Approximate quantity		Remarks
1	Wall panel	Accommodation	Asbestos	Insulation	2500.00	kg	
2	Wall insulation	Engine control room	Lead	Perforated plate	0.01	kg	Cover for insulation material
			Asbestos	Insulation	25.00	kg	Under perforated plates

For identical or common items, such as but not limited to bolts, nuts, and valves, there is no need to list each item individually.

Pipes and Cables The names of pipes and of systems, including electric cables, which are

often situated in more than one compartment of a ship, should be described using the name of the system concerned. A reference to the compartments where these systems are located is not necessary as long as the system is clearly identified and properly named.

“Location” Column It is recommended to prepare a location list which covers all compartments of a ship based on the ship’s plans (e.g., general arrangement, engine room arrangement, accommodation, and tank plan) and on other documentation on board, including certificates or spare parts’ lists. The description of the location should be based on a location such as a deck or room to enable easy identification. The name of the location should correspond to the ship’s plans so as to ensure consistency between the Inventory and the ship’s plans. For bulk listings, the locations of the items or materials may be generalized. For example, the location may only include the primary classification such as “throughout the ship.”

The description of location of pipes and electrical systems, including electrical systems and cables situated in more than one compartment of a ship, should be described for each system concerned. If they are situated in a number of compartments, the most practical of the following two options should be used:

1. Listing of all components in the column
2. Description of the location of the system using an expression such as those under “primary classification” and “secondary classification”

“Approximate Quantity” Column The standard unit for approximate quantity of solid hazardous materials should be kg. If the hazardous materials are liquids or gases, the standard unit should be either m³ or kg. An approximate quantity should be rounded up to at least two significant figures. If the hazardous material is less than 10 g, the description of the quantity should read “<0.01 kg.”

Maintenance and Continuity of Part I of the Inventory

To maintain the IHM notation, it is the responsibility of the shipowner to keep the Inventory updated at all times. The shipowner should ensure that the Inventory is maintained with current information.

Whenever there are new installations (machinery, equipment, hull coating) added to the vessel that includes materials listed in

Table 1, as permitted by the Hong Kong Convention, the Inventory is to be updated where applicable. The shipowner has the right to request an additional survey if there are significant amount of changes to the Inventory.

Maintenance of the IHM

There is a maintenance manual which is to include the identity of the designated person; a system for maintaining and updating of the Inventory; records of new installations, repairs, maintenance, and modifications to a ship; and records of changes to the Inventory.

Part I of the Inventory should be appropriately maintained and updated, especially after any repair or conversion or sale of a ship (China Classification Society 2016). The maintenance of Part I of the Inventory is to be based on Material Declarations furnished by suppliers for equipment, parts, material, etc. Material Declarations are to be obtained for all purchases that may impact a ship’s structure and equipment (e.g., materials, machinery or equipment, spare parts, etc.). If any of the Material Declarations contain materials listed in Tables 1 or 2 above the threshold values, Part I of the Inventory is to be updated accordingly with the use of these materials, equipment, or spare parts onboard the ship.

If any machinery or equipment is added, removed, or replaced or the hull coating is renewed, Part I of the Inventory should be updated according to the requirements for new ships as stipulated in Chapter 3. Updating is not required if identical parts or coatings are installed or applied.

Shipowners should implement the following measures in order to ensure the conformity of Part I of the Inventory:

1. To designate a person as responsible for maintaining and updating the Inventory (the designated person may be employed ashore or on board).
2. The designated person should establish and supervise a system to ensure the necessary updating of the Inventory in the event of new installation.

3. To maintain the Inventory including dates of changes or new deleted entries and the signature of the designated person.
4. To provide related documents as required for the survey or sale of the ship.

The deletion of equipment and/or parts of the ship's structure previously classed as "potentially containing hazardous materials" in the Inventory was supported with reasons and evidence that the equipment, system, and/or area does not contain hazardous materials or which has subsequently been sampled and found to contain hazardous material, which has been identified in the revised Inventory or a supplement to the Inventory thereof.

Continuity of the IHM

Where there is a change of flag, owner, or operator of the vessel, the contents of the Inventory, supporting documents, and maintenance manual are to be confirmed as containing the latest information and passed on to the next shipowner.

A new designated person responsible for the Inventory and system to maintain and update the Inventory is to be established by the subsequent owner or operator of the vessel.

Survey of Part I of the Inventory

The Inventory is to be subject to surveys for the issuance and maintenance of the IHM notation.

Initial Survey

The initial survey is to be carried out with an Inventory that has been reviewed without outstanding technical comments. The survey is to verify that the Inventory, especially the location of hazardous materials, is consistent with the arrangements, structure, and equipment of the vessel through an onboard visual inspection.

Annual Survey

The Inventory will be subject to an annual survey in the course of completing other annual and periodical surveys. The annual survey is to verify the following:

1. The Inventory has been maintained and updated to reflect changes in vessel structure and equipment based on the records in the maintenance manual, to the satisfaction of the surveyor.
2. "Materials Declaration" and "Supplier's Declaration of Conformity" have been collected for purchases of materials, machinery or equipment, coating renewal, and spares from the date of the last survey verification of the Inventory or Inventory supplements thereof. Deletion of equipment and/or parts of the ship's structure previously classed as "potentially containing hazardous materials" from the Inventory complies with the requirements.
3. The Inventory, especially the location of hazardous materials, is consistent with the arrangements, structure, and equipment of the vessel through an onboard visual inspection.

Additional Survey

When a ship undergoes a replacement or repair of the structure, equipment, systems, fittings, arrangements, or material, which has a significant impact on the ship's Inventory, the shipowner is to request an additional survey of the Inventory.

The additional survey is to be carried out with an updated Inventory or an Inventory supplement that has been reviewed by engineering without outstanding technical comments. The survey is to verify that the updated Inventory or additional supplements to the Inventory, especially the location of hazardous materials, are consistent with the arrangements, structure, and equipment of the vessel through an onboard visual inspection.

Synonyms

SeSA_m

Definition

Jacket refers in the oil and gas exploration and production to the steel frame supporting the deck and the topsides in a fixed offshore platform (<https://www.2b1stconsulting.com/jacket/>).

Basic Performance and Characteristics

There are multiple types of offshore platforms depending on the applications and the depth of the water. Fixed platforms are generally used for explorations at shallow water production. Jacket platform, one of the fixed platforms which are often used for production platform, has good adaptability, high safety, and high reliability. It also has the advantage of simple structure and low cost and has become the primary structure form in the exploitation of offshore oil and gas resources for more than half a century.

The steel jacket platform is fixed to the seafloor by means of piling. Since its first use in the 6-m-deep waters of the Gulf of Mexico in 1947, the steel jacket platform has been rapidly developed. By 1978, its depth had reached 312 m. So far, there are about 2,000 large- and medium-sized jacket-type offshore platforms built in the world, and the working water depth has reached nearly 500 m.

Jacket Platform Development History

The world's first fixed offshore platform was built in 1887; it was installed in one oil field in California, USA. But it is a wooden trestle structure. After World War II, many advanced scientific and technological achievements were put into use for marine and offshore development. In 1947, the world's first real steel jacket platform was successfully installed at a depth of 6 m in the Gulf of Mexico, creating a new era of offshore development. Since then, the offshore platform has been rapidly developed, and jacket platform has become the dominating structure of the offshore platforms in the middle shallow sea. At the end of the 1970s, steel jacket platforms were installed in the sea site with more than 300 m. By 1990, a huge jacket platform with a height of 486 m was successfully installed at the site with water depth of more than 400 m in the Gulf of Mexico. Jacket platform has gradually expanded to deeper water area and harsher marine environments over the past years. Jacket platforms are

mainly designed and built for exploration and exploitation of marine resources, mainly for oil and natural gas resources. So far, there are about 2,000 large- and medium-sized jacket-type offshore platforms existing in the world, and the working depth has reached to 500 m.

Features of Jacket Platform Structure

There are many types of steel jacket offshore platforms, and the cost-effect determines the choice of platform type, for example, typically in the deepwater area, using all fully functional, self-contained monolithic platforms. In shallow waters, multiple separate platforms with different functions are mostly welcomed, for example, supply platform, drilling platform, production platform, living platform, auxiliary platform, etc.

The jacket platform has three main structural parts including topside module, jacket, and pile foundation.

Topside Module

The topside module, also called deck structure, includes platform decks, bulkheads, deck pillars, and truss structures, of which primary function is to provide enough space for drilling or production at sea to deploy drilling or recovery equipment, auxiliaries, various kinds of living equipment, and helicopter lift. The topside module includes two kinds of structural forms, namely, the monolithic and block structure.

All deck structures are in principle composed of three-dimensional steel components. The main load-bearing components are divided into three forms, plate girder, box girder, and truss. Plate girders and box girders consist of a pallet. The girders that make up the truss are tubular or profiled (I-beams, channel.). In the case of monolithic structures, the equipment is installed after the construction of the structure; in the block construction, the deck foundation is constructed in prior, and then the module is transferred and fixed on the jacket structure and foundation.

Jacket Structure

Jacket is the supporting structure of the jacket platform. Jacket structure is a steel or steel welded

frame and is actually a three-dimensional flat panel rack or plane truss consisting of a three-dimensional space truss structure. These trusses are mainly composed of large-diameter pipe piles (chords), small-diameter pipe, small-sized profiles, and horizontal, vertical, and diagonal strut composition. Tubular node structures are formed at the intersection of the tubular members. General tube nodes are chord (namely, larger diameter tube member in the tube node) wall thickening or other measures to be strengthened. The main role of the jacket structure is to support the topside module and the platform for offshore installation and construction. The jacket's legs are as piling positioning and orientation. In addition, jacket can also be used to connect the ship, in order to facilitate the supply boat off the platform.

Pile Foundation

For most fixed marine structures, the external load and its own weight mostly rely on the pile foundation. The role of the pile foundation is to fix the platform to the seafloor and to withstand the lateral loads and vertical loads and has strong anti-seismic capability. The pile foundation penetrates into the subsoil. Commonly, pile foundation consists of single pile or group pile. The load of the topside module and jacket structure passes through the pile foundation to the seabed (Fig. 1).

Deepwater Jacket Platform

With the development of oil and gas production into deep waters, the deepwater jacket platform has come into being. The main features of deepwater jacket platforms are high, large, heavy, and complex, so weight control is one of the most critical technologies. It is a gravity-type structure which means under constant environmental load, structural self-weight, buoyancy, and ballasting can maintain its own stability. If this equilibrium condition can't be met, thus there will be excessive structural subsidence and horizontal slip or even the whole overturning of the jacket platform. Therefore, compared with shallow water jacket platform, the main challenge of deepwater jacket platform is to control the weight and center

Jacket Platform,**Fig. 1** Components of jacket platform

of gravity of the upper part of the platform. Designers are required to apply the relevant norms and standards reasonably according to the oilfield conditions and strictly control the weight of the upper facilities. As a result, jacket platform applications have water depth limitations. Averagely, deepwater jacket platform is used within the water depth no more than 300 m, but there are already some examples of deepwater jacking jackets installed with a depth more than 400 m in the world (Fig. 2).

Main Challenges in Jacket Platform Application

The main challenges in jacket platform design, installation, operation, and decommissioning

include ductile collapse, fatigue, and ultimate strength.

1. **Ductile collapse.** With the increasing of height of jacket platform, ductile collapse has becoming one of its major failure modes. Because the complexity of large jacket platform, its ductility in different directions is versatile. In the direction with high collapse redundancy, more loads will transfer through this path, and more structural components can effectively bear the load and thus improve the anti-collapse ability of the platform.
2. **Ultimate strength.** Ultimate strength is one critical issue when designing and constructing a jacket platform. Under severe sea states, wave, wind, and current will

Jacket Platform, Fig. 2 A deepwater jacket platform being towed

induce gigantic loads on the jacket platform. The ultimate load-bearing capability needs to be estimated accurately during the design stage. The calculation of ultimate strength often includes the consideration of plastic-elastic characters of the steel material of the jacket platform. In addition, another issue is also often considered, post-collapse strength, which fully considers the material plasticity to assess the strength of the jacket platform after collapse happens.

3. **Foundation failure.** Failures of pile foundation and the ground foundation have become one of the main control factors of the ultimate bearing capacity of the platform. When the platform reaches the limit state, the double plastic hinge is formed on the upper part of the pile leg, resulting in the cause of great reduction of ultimate bearing capacity of the whole platform.
4. **Wave slamming.** The design of the platform should ensure that the deck air gap has

sufficient safety margin. When the wave reaches a certain height, the jacket and the upper block connection unit have to endure the wave slamming effect and can be plastically deformed. When the plastic deformation expands to form a plastic hinge, it will cause the upper part of the platform to roll over and collapse, which is consistent with the observed platform failure mode after typhoon. Therefore, it is necessary to consider the effect of the wave load on the deck in the safety assessment of the existing offshore platform (especially in the case of serious settlement).

Definition

A *jack-up platform* or a self-elevating unit is a type of mobile platform that consists of a buoyant hull fitted with a number of movable legs, capable of raising its hull over the surface of the sea. The buoyant hull enables transportation of the unit and all attached machinery to a desired location. Once on location the hull is raised to the required elevation above the sea surface supported by the sea bed. The legs of such units may be designed to penetrate the sea bed, may be fitted with enlarged sections or footings, or may be attached to a bottom mat. Generally *jack-up platforms* are not self-propelled and rely on tugs or heavy lift ships for transportation (https://en.wikipedia.org/wiki/Jackup_rig).

Basic Characteristics of Jack-Up Platform

The jack-up platform is a type of removable drilling platform which stands on the seabed through its three or four legs when it is operating. The jack-up platform is a platform for offshore operations consisting of a barge-shaped hull and several legs that can be raised and lowered, as shown in Fig. 1. The legs serve to support the hull and lift or lower the hull. When the jack-up platform needs to reach the working sea area, the legs will lower the hull to the sea surface and allow the hull to float on the sea surface by the hull's buoyancy; thereby the tug can move the platform. When the jack-up platform reaches the target working area,

Jack-Up Platforms, Fig. 1 A jack-up platform

the legs raise the hull to a certain height above sea level, so that drilling, oil extraction, or other work can start.

The installation of jacket-up platform is a critical process. The different phases of jack-up installation are indicated in Fig. 2.

Jack-up platforms can work at water depth from 4 m up to 170 m. If the water depth is too large, the legs of a jack-up platform will be very long, which bring high cost and much technical difficulty.

History of Jack-Up Platform

Jacket-up platform has a long history. Figure 3 shows the number of jack-up rigs built between 1965 and 2005. It is indicated in Fig. 3 that in the early of 1980s, there were many jack-up platforms built, about 100 jack-up rigs from 1980 to 1981 and about 120 jack-up rigs from 1982 to 1983, when jacket-up platform reached its top in the history.

As early as the year 1869, American Samuel Lewis first applied for a jack-up rig patent (Chen

Jack-Up Platforms,

Fig. 2 The different states of a jack-up platform

Jack-Up Platforms,

Fig. 3 Number of jack-up rigs built between 1965 and 2005

and Li 2007). It was not until 1954 that the world's first jack-up rig DeLong No. 1 (also called Offshore No. 51) (Jackup rig. 2018) appeared. DeLong No. 1 has ten legs, each leg 48.8 m long and 1.8 m in diameter, using the jacking system designed by L. B. DeLong. In 1956, the first three-legged jack-up rig Zapata Scorpion was handed over to Zapata Offshore, which was designed by LeTourneau (Jackup rig. 2018) and uses innovative lattice type legs and rack and pinion jacking system. Scorpion platform, with 56.7 m length, 45.7 m width, 42.7-m-long legs, and 4000 t weight, is the prototype of modern jack-up platform. In 1963, the first oblique-legged platform Dixilyn250 (Drilling Rigs Built in US Shipyards 2015) designed by LeTourneau was completed. In 1966, Offshore Orion (Orion), the first jack-up platform which can work permanently at the North Sea emerged (Fig. 4).

With the advent of better materials and improvements in technology, the water depth in which jack-up platforms can work continues to increase. In 2003, the jack-up platform Bob Palmer of type Super Gorilla XL, owned by LeTourneau Company, got a record depth of 168 m in the Gulf of Mexico. Its height is 273 m.

So far, jack-up platforms account for about 60% of the number of offshore removable drilling platform.

Main Characteristics of Jack-Up Platform

As mentioned earlier, a jack-up platform consists of a hull and several legs. As the hull and legs can be vertically moved relatively, there also exists a jacking system, including the lifting device on the hull, the lifting structure on the legs, and the

Jack-Up Platforms, Fig. 4 Major development milestones for jack-up rigs

power system. Currently, there are two main types of jacking systems: electrohydraulic type and electric rack and pinion type. In the electrohydraulic type, the movement of the piston rod in the hydraulic cylinder is used to lift or lower the legs with the help of the lock pin. This type has the advantage of not requiring complicated transmission mechanism, small size, and flexible control. The disadvantage is that the lifting is not continuous and slow. This type is commonly used in jack-up platforms in shallow waters. In the electric rack and pinion type, the gear fixed on the hull is driven by the motor through the gear mechanism to lift or lower the legs by meshing the rack fixed on the legs. When the legs stand on the seabed, the continuous movement of the hull relative to the legs can be achieved. Relatively speaking, this type has the advantage of higher speed, successive lifting and lowering, and flexible operation. However, a large and complicated transmission mechanism is required. Besides, this type is large in size and requires high manufacturing techniques for gears and racks. This type is often used in the jack-up platform working in the deep sea waters.

When the jack-up platform is in operation, the legs need to be inserted into the seabed. Therefore, the influence of the seabed soil must be considered. If the soil conditions are not good, for example, the soil is very soft, the mat structure or spudcan is often placed in the bottom of the

Jack-Up Platforms, Fig. 5 A jack-up platform with a mat structure

jack-up platform. The purpose is to make the support area larger so that the legs will not sag too deep. Figure 5 shows a schematic diagram of a jack-up platform with a mat structure.

Jack-Up Failure Accidents

Compared to other fixed platforms, jack-up platforms have a higher failure rate. Leijten and

Jack-Up Platforms, Table 1 Total loss for jack-up platforms and fixed platforms from 1970 to 1989

	1970–1979	1980–1989
Jack-ups	162	97
Fixed platform	7	1

Efthymiou (1991) investigated the accident data for both types of platform from the year 1970 to 1989 and gave the findings, see Table 1.

The failure modes of jack-up platforms include the following:

- (a) **Punch-Through:** the punch-through is an accident that the legs suddenly penetrate the soil due to the unpredictable drop in bearing capacity of the soil. This accident may cause damage to the legs or even result in the tilting of the whole platform. This is the most frequently happened accident for jack-up platforms.
- (b) **Rack Phase Difference:** “eccentric spudcan loading can result in a vertical difference in height between the chords within a leg” (Koole 2015). If the Rack Phase Difference (PRD) becomes excessive, it may result in the buckling of the bracing in the legs. PRD is found to more frequently happen in modern jack-up platforms.

Lietaert (2011) summarized a list of the risk associated with the foundation, and Table 2 presents part of them.

The Main Threat of Jack-Up Platform Transport: Stability Issue

As can be seen from Fig. 2, during towing the jack-up platform is buoyed by the hull, and the legs are raised to the very top. In this case, the windward area of the entire jack-up platform becomes larger, and the center of gravity becomes higher, which make the towing stability worse.

According to the requirements of classification society, the towing stability of a jack-up platform includes intact stability and damage stability.

Jack-Up Platforms, Table 2 Jack-up rig foundation associated risks

Risk	Methods for evacuation or prevention
Punch-through	(a) Seismic survey (b) Soil sampling and geotechnical testing
Settlement under storm or bearing failure	(a) Seismic survey (b) Soil sampling and geotechnical testing (c) Adequate preloading
Sliding failure	(a) Seismic survey (b) Soil sampling and geotechnical testing (c) Modify the footings
Scour	(a) Bathymetric survey (b) Surface soil sampling and analyze seabed current (c) Inspect footing foundations regularly (d) Install scour protection
Mud slides	(a) Side scan sonar and seismic survey (b) Soil sampling and geotechnical testing

Intact stability means the stability of the hull without damage. Damage stability is the stability of the vessel after the tank has been damaged and flooded. Obviously, the stability of the hull is worse if the tank is flooded. Whether the intact stability and the damage stability meet the requirements is measured by the allowable height of the center of gravity. In other words, if the actual height of the center of gravity in a draft is calculated to be less than the allowable height of the center of gravity during the towing, the stability in this operating condition is deemed to meet the requirements of the classification society.

Punch-Throughs of Jack-Up Platforms

Basic Characteristics of Punch-Through

Punching through is one of the most critical types of incidents for jacket-up platform. The accidents caused by punch-through have a big proportion of the number of jack-up platform accidents, as shown in Fig. 6, about 53%. From Fig. 6, the punch-through accidents happening during the preloading

Jack-Up Platforms, Fig. 6 Different types of accidents in jack-up rigs (Dier et al. 2004)

or jacking up account for 14%, and the accidents during hurricane or storm account for 8%.

The punching through incident happens due to the platform's losing of its capability of standing on the seabed. The seabed soil condition of the jack-up platform working area is complex. When spudcans are located on the seabed in which upper layers of soil are hard and lower layers of soil are soft, the jack-up platform may rapidly sink or tilt due to the loss of support of the soil where a specific leg rests. Punch-through causes the damage to the rig, the deformation of legs, or even platform sinking. So punch-through seriously affects the safety of the platform. Punch-through of a jack-up platform is defined as: "An unexpected jack-up footing rapid settlement resulting in consequential lost drilling time" (Osborne and Paisley 1996).

As a matter of experience, incidents caused by punch-through mainly occur during lifting, preloading, or the stormy weather.

A Punch-Through Accidents

In November 1996, a punch-through incident happened to the Maersk Victory jack-up platform (Maersk Victory); see Figs. 7 and 8.

The accidental process of Maersk Victory is described as below.

The Maersk Victory was towed onto the site by the Massive Tide, once offloaded from the Super Servant 3. Before installation, the position surveyor noticed that there was no site survey for this rig and they attempted to make a site survey on the date of 16 Nov. The first attempt at jacking up started at 6:30 am and aimed to achieve the 2 m preload air gap. It was successfully achieved. At the time of 8:25 am, the helicopter arrived, and then the preloading continued from 10:00 am. However, at 10:32 am, in one third of the way through the preloading, the rig listed to starboard suddenly, and the deck was washed by the sea water. After two or three punches, the rig stabilized. Inspections found that legs #1 and #2 were severely damaged. Then divers cut the hull free of the legs to allow the hull to be towed back to a safe anchorage near Port Adelaide. The legs of the rig were salvaged using the Dock Express 10 over December 1996 and January 1997 and then delivered together with the hull to the Far East Livingston Shipbuilding company in Singapore for repairs.

Jack-Up Platforms,

Fig. 7 The punch-through of Maersk Victory

Jack-Up Platforms,

Fig. 8 The punch-through of Maersk Victory

This was an unsuccessful preloading of the jack-up platform, which caused severe damage to the legs and resulted in lost drilling time. The South Australia Department of Mines and Energy Resources (MESA) undertook an investigation in May 1997. It was concluded that there was a failure to fully evaluate the geotechnical data of the sub-sea sediments.

Jack-Up Foundation Assessment

Jack-up foundation site assessment is important for the jack-up platform to decrease the risk of punch-through. The absence of foundation assessment may cause severe punch-through of

the jack-up platform. The jack-up foundation site assessment usually starts with a review of the site geophysical survey report, which includes bathymetry, side-scan-sonar, sub-bottom profiling, and a shallow gas prognosis (Osborne and Paisley 1996). This geophysical survey report may be supplemented with the geotechnical borehole data.

Borehole Data Requirements

For jack-up foundation assessments, it is important to acquire continuous soil data throughout the borehole depth. The borehole depth is the minimum between the anticipated spudcan

penetration depth plus one spudcan diameter and 30 m.

The borehole investigation could be continuous soil sampling test or in situ piezocone penetrometer testing. As thin layers or subtle variations in soil parameters could significantly change the spudcan bearing capacity and penetration performance during unit installation preloading and subsequent operation, the continuity of data is highly important for jack-up foundations. In highly variable soil conditions, it is necessary to conduct both continuous sampling and in situ test.

Applicability of Soil Laboratory Tests to In Situ Condition

The soil laboratory test is a frequently method to acquire the soil strength profile in a specific situation. It is operated in the laboratory, which can use many instruments. However, there is a debate regarding the applicability of the soil strength derived from small-scale laboratory test compared to the in situ soil strength. First, the zone of the soil during the laboratory test has smaller dimension than that of the soil beneath and around a spudcan. The scale effects have to be considered. The presence of fissures and failure surfaces within the soil, which may not be identified during the soil sample test, could make the scale effects worse. Second, the change in pressure from the in situ location may affect the accuracy of the laboratory test. When the soil is brought to the surface, the gas expansion and soil rupture may diminish the usefulness of the laboratory strength test data.

The laboratory soil test should give due consideration to the scale effects and the change in pressure of the soil mass.

Jellyfish Bloom

Dong Sun

Key Laboratory of Marine Ecosystem Dynamics, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, China

Synonyms

Continuous Plankton Recorder (CPR)

Definition

Jellyfish bloom was an ecological disaster caused by the increasing number of pelagic cnidarians. It was considered as potential problems only relatively after the 1950s (Purcell et al. 2007). In recent years, reports of jellyfish blooms are rapidly increasing from various information sources, e.g., scientific papers, news from TVs or newspapers, data reports of fishery organization or documentary film, and from disparate regions of the world, e.g., Bering Sea, Sea of Japan, Yellow Sea, and Black Sea (Brodeur et al. 2002; Kideys 2002; Uye 2008; Dong et al. 2010). The jellyfish blooms

are widely considered as serious threats to marine fisheries, tourism, coastal power plants, and the whole ecosystem, especially in coastal and offshore areas. The mechanisms of bloom and collapse of jellyfish population are complicated and vary with the environment (Graham et al. 2001; Purcell 2012). The present section will introduce several aspects of jellyfish bloom.

Introduction

“Jellyfishes” are not a clade, either in taxonomy or in phylogeny. Jellyfish is the common name of various medusae for a long time. This common name included the Ctenophore and Siphonophore based on comparable function in ecosystem and status in trophic webs since the 1990s (Mills 1995). The term is so simple and broad that it causes a lot of confusion and misunderstanding in applications (Lucas and Dawson 2014). Thus, it is essential to distinguish the composition in taxonomy. To be precise, “true” jellyfishes equal to pelagic cnidarians, including Scyphomedusae, Cubomedusae, Siphonophore, and Hydromedusae, but the term is also regarded to cover pelagic ctenophores in practice (Lucas and Dawson 2014).

“Jellyfish bloom” is a widely used but easily confusing concept, not only in public media but also in scientific papers or reports. Consistency of term is essential for describing the phenomenon, understanding the causes and consequences, and preparing appropriate crisis response program. Following the summary and discrimination by Lucas and Dawson (2014), a “true” bloom was able to be considered as a part of seasonal life cycles of organisms, which meant normal population of certain species had a potential instinct to bloom when the environmental conditions were suitable. In contrast, an “apparent” bloom generally indicated a local or sudden increase of population, which was usually due to temporary chemical or physical phenomena or longer-term accumulation in enclosed or semi-enclosed habitats (such as aggregation at fronts or local advection to a new location). Besides, we also need to

make a further distinction between “aggregation” and “outbreak” of population. An “aggregation” of individuals indicates a short-term increase of abundance or biomass in the absence of increased population growth, possibly, due to passive drifting in currents or/and active swimming of individuals. An “outbreak” means a sudden increase in population size, showing an unusually high abundance or biomass compared with other years, and usually caused by anthropogenic change in ecosystems or climate change. Thus, an outbreak of population largely equals to a “unnatural” bloom. Below, we discuss the “unnatural” bloom or outbreak of population, which is the narrow concept of jellyfish bloom.

Causes of Jellyfish Bloom

Eutrophication

Eutrophication is widely considered as one of important factors contributing to jellyfish blooms. Most simply, increased nutrients often lead to greater biomass at all trophic levels, through the bottom-up control (Nixon 1995). More food for jellyfish increases the body growth and reproduction rates of them and the growth rate of population (Moller and Riisgard 2007). Besides, eutrophication shifted the N:P ratios of seawaters. That could alter the pelagic food web from diatom-based to flagellate-based, which might be conducive to jellyfish blooms (Purcell 2007). Eutrophication has another additional effect: algal bloom stimulated by abundant nutrients would reduce the transmittance of seawaters, and decreased light penetration may benefit nonvisual gelatinous predators over visually feeding fish (Aksnes et al. 2009).

Hypoxia

Hypoxia in coastal and offshore waters is one serious consequence, which is largely due to eutrophication and hydrodynamic condition in these regions. Fish die in hypoxic environment or escape from hypoxic waters, but many jellyfishes (though not all) showed stronger tolerance than their competitors in food web (Purcell

et al. 2007). This advantage in competition promotes their population growth.

Substrate Additions

Human activities have greatly changed the coastal sediment environment. Harbors and aquaculture rafts are most important and common artificial structures. They provide an ideal habitat for the sessile stages of scyphozoans and hydromedusae, which are found attached to hard surfaces in harbors and aquaculture rafts (Duarte et al. 2013). In addition, these artificial structures also provide eutrophic water and appropriate lagoons for the reproduction and growth of jellyfish (Lo et al. 2008).

Transportation of Exotic Species

There have been many reports of exotic species introduction for jellyfish, e.g., *Phyllorhiza punctata* and *Mnemiopsis leidyi* (Kideys 2002; Verity et al. 2011; Costello et al. 2012). Once these exotic species are introduced into an environment free of their natural predators, the population of invasive species always show rapid or even explosive growth after they adjust to new environment (Parker et al. 2003). The transportation of species included both human influence and natural process. For example, the most damaging introduced jellyfish, *M. leidyi*, was originally considered to transport within ballast waters of intercontinental shipping vessels (Costello et al. 2012). However, a recent and more detailed study showed that the ocean currents played an important role in secondary spread of this species when they arrived at Europe and lead to invasion corridors in western Eurasia (Jaspers et al. 2018). Besides, global warming makes this trend worse (Stachowicz et al. 2002).

Overfishing

Overfishing is regarded as a key environmental driving factor that could stimulate population bloom of jellyfish, probably because of reduced competition from zooplankton when the abundance of forage fish decreases (Purcell 2012). A nice example is that the abundance of jellyfish significantly increased after the herring stock collapsed in the northern Irish Sea by the long-term

data from Continuous Plankton Recorder (CPR) (Lynam et al. 2011).

Climate Change

Climate changes are also considered to affect the population dynamics of jellyfish. Global warming is an important aspect of climate change and causes serious consequences for ocean ecosystems (Danovaro et al. 2004; Doney 2006). Most of the studies about temperate jellyfish species show greater and more rapid production at higher temperature, and salinity also has significant effects, especially for estuarine species (Purcell 2005). In addition to those direct influences, climate change also showed some more complicated and unpredictable indirect impacts on population dynamics of jellyfish. For example, global and local primary production clearly corresponded with sea surface temperature and dissolved iron in ocean (Gregg et al. 2003; Behrenfeld et al. 2006), and it will influence upper trophic levels through the bottom-up control. Climate change also alters the structure of food web, especially related to the predators of jellyfish, e.g., turtles (Hawkes et al. 2009; Carman et al. 2014). And this will make an impact on population dynamics of jellyfish by top-down control.

Global Trend of Jellyfish Blooms

As mentioned above, public perceptions about jellyfish blooms are increasing globally, based on reports, news, and scientific papers. However, some studies suggested that there was no indubitable evidence for a global increase in jellyfish and found worldwide oscillations with an approximate 20-year periodicity in jellyfish populations. A rising phase during the 1990s largely caused the perception of a global increase in jellyfish abundance (Condon et al. 2012, 2013). A recent study also indicated that complex spatial structure of jellyfish population would significantly affect and disturb the density estimate of them in a bay (Shahrestani et al. 2020). But regardless of the global trend, local jellyfish blooms have still caused serious consequences (see below).

Ecological and Societal Threats of Jellyfish Blooms

Threats to Aquaculture and Fishing

The jellyfish blooms pose serious threats to fishing and natural fish populations, through various pathways, including predation on fish larvae and juveniles, competition on food, and hindrance of fishing activities (Purcell and Sturdevant 2001; Uye 2008; Pereira et al. 2014). On the other hand, a growing number of studies also supported the direct damage of jellyfish to aquaculture species (Baxter et al. 2011; Dong et al. 2017) (Fig. 1).

Threats to Tourism

Several jellyfish species are proved to be harmful to humans, such as the moon jellyfish *Aurelia* spp. (Dong 2019). These threats could be more serious for sensitive people (Burnett et al. 1988). Therefore, if these dangerous jellyfish break out near tourist attractions, it will cause potentially significant losses to local tourism industry.

Threats to Power Plants

Although several early warning and monitoring tools have been developed to avoid above interfere (Kawasumi et al. 2001; French et al. 2018), the reports of interfere from jellyfish blocks to

Launching Technology

Fengsheng Sun
School of Navigation and Naval Architecture,
Dalian Ocean University, Dalian, China

Definition

Ship launching is the procedure to move the ship from the construction area to the waters to float, by means of a certain launching equipment, after most of the ship construction project is completed.

Introduction

Ship Launching Methods

Ship launching, according to its principle, can be divided into three categories: gravity launching, floating launching, and mechanizing launching.

Ship launching, according to the direction of the ship's entry into the water, can be divided into side launching and stern launching.

Ship launching, according to its process, can be divided into greased slipway launching, steel roller slipway launching, and trolley launching.

By combining the above methods based on feasibility, ship launching can be realized through many ways (Table 1).

The new ship-launching methods include air bag launching, water cushion launching, etc.

Ship Gravity Launching

Gravity launching is a launching method in which the ship enters the water along the slipway of the building berth under its own gravity. Generally, the direction of entry into the water can be longitudinal (end launching) and horizontal (side launching) (Liu and Wang 2011).

End Launching

End launching (Xu 2005) is suitable for ships of different types and launching weights. According to different slide mediums of the slipway, the inclined building berth slipway can be divided into greased slipway and steel roller slipway, so end launching can be divided into longitudinal greased slipway launching and longitudinal steel roller slipway launching.

Longitudinal Greased Slipway Launching

When launching, the keel block, side keel block, and shores are first removed, so that the weight of the ship acts on the sliding way and slipway, and the trigger controls the ship not to slide. When the tide reaches a certain height, the trigger is released and the ship, together with the bracket and sliding way, slides into the water along the slipway. When the stern of the ship reaches the water, the stern of the ship begins to receive buoyancy, and the ship continues to slide until the whole ship floats up by buoyancy (Ji 2005) (Fig. 1).

Longitudinal Steel Roller Slipway Launching

This type of launching uses steel rollers instead of launching grease, by rolling friction instead of sliding friction, thus further reducing the friction between the sliding way and the slipway. Steel roller-launching devices include slipway, steel rollers, distance keeping device, combined type sliding way, etc. (Fig. 2).

Launching Technology, Table 1 Classification of traditional ship launching

Principle of launching	Water entry method	Launching equipment
Gravity	End launching	Greased slipway, steel roller slipway, etc.
	Side launching	Greased slipway, oak slipway, etc.
Floating	End launching	Shipbuilding dock, floating dock, etc.
Mechanizing launching	End launching	Longitudinal railway slipway, longitudinal inclined cradle slipway, etc.
	Side launching	Side slipway with top and lower railway, sideslipping cradle slipway, etc.
	End launching	Ship lift, crane, etc.

Launching Technology, Fig. 1 Schematic diagram of longitudinal greased slipway

Launching Technology,

Fig. 2 Longitudinal steel roller slipway

Launching Technology,

Fig. 3 Schematic diagram of gravity side launching

Side Launching

Side launching is the sliding of the ship along the width of the ship, which is divided into two types. The first type is the launching with the slipway extending into the water. The ship sits on a wedge-shaped sliding way and slides into the water longitudinally along the slipway. The ship always stays longitudinal during launching, and this type of launching is called side-floating launching. The other type is the launching with the slipway not extending into the water. The end of the slipway is interrupted at the vertical quay wall. When launching, the ship falls into the water, together with the sliding way and poppet,

and balances itself with its own buoyancy and stability, so this type of launching is called side drop-type launching (Xu 2005) (Fig. 3).

Ship Floating Launching

Ship floating launching is a launching method in which water is injected into the ship construction site (dry dock, floating dock, etc.) so that the ship can naturally float on its own buoyancy (Liu and Wang 2011).

Dry Dock Launching

Dry dock (Fig. 4) is a hydraulic structure built on land to facilitate ship launching and jacking onto

Launching Technology, Fig. 4 The dry dock of a shipyard

block based on the principle of floating, which is generally composed of dock chamber (dock bottom and dock wall), dock gate, and water-pumping station.

During ship launching, water is injected into the dock chamber, and the ship floats by water buoyancy. When the water level in the dock is level with the water level outside the dock, the dock gate is opened and the ship is towed out of the dock (Fig. 5).

Floating Dock Launching

The floating dock has a huge concave space with walls on both sides and open ends in the front and rear. It is a trough punt with a special structure. The dock wall and dock bottom on both sides are box-shaped structures, which are divided into several closed cabins along the longitudinal and horizontal directions. Some cabins are called water tanks, which are used for water injection and drainage to make the dock sink and float.

Usage of the floating dock: First fill in the floating dock water tanks with water, and sink

the floating dock to the depth with which the dock could meet the draft requirements of the docked ship. Then use the winch on the top of the dock wall to pull the ship into the dock and remove the water in the water tanks. The floating dock gradually floats up until the top surface of the dock floor is exposed to the surface of the water, and along with the dock floor, the ship to be repaired is also exposed above the water surface, so that the ship repair work can begin (M et al. 2014) (Fig. 6).

Ship Mechanizing Launching

Mechanizing launching is the use of mechanized facilities to complete the process of ship launching.

Mechanizing Launching with Longitudinal Railway Slipway

The ship is on the integral or sectioned ship slipway with rollers. When launching, the ship slipway that carries the ship is pulled through steel cables and pulleys by the winding engine, and the ship is sent

Launching Technology,
Fig. 5 Dry dock launching

Launching Technology, Fig. 6 Floating dock

into the water along the track on the inclined building berth until it floats successfully (Fig. 7).

Mechanizing Launching with Wedge Type Launching Cradle Slipway

The slipway launching cradle used is a wedge-shaped cradle with a horizontal or approximately horizontal poppet surface. Therefore, bow

pressure will not be generated in ship launching with this method. The launching method is simple and reliable, suitable for the launching and jacking onto block of larger ships (Figs. 8 and 9).

Ship Lift Launching

Ship lift is a lifting platform set up close to the launching wall, where the hydraulic or windlass

Launching Technology,
Fig. 7 Longitudinal
railway slipway

Launching Technology, Fig. 8 Longitudinal slipway of wedge launching

Launching Technology, Fig. 9 Horizontal slipway of wedge launching cradle

Launching Technology,
Fig. 10 Ship lift

winch can be used to vertically lift the platform for ship launching or jacking onto block. In ship launching, the lifting platform is first aligned with the berth slipway and fixed by means of the winch, and the ship is moved, from the building berth to the lifting platform, and is released from the fixation. Then the winch is started, and the lifting platform, together with the launching ship, is lowered into the water. The ship has a draft gradually and floats, and the launching is completed (Ma and Xuexing 2019) (Fig. 10).

Choice of Ship Launching Methods

The ship launching facility is closely related to the layout of the building berth, both of which are extremely important production facilities in the shipyard. When ship launching, the layout and technological process of the shipyard will be comprehensively considered to determine a reasonable launching method and launching facilities.

There are many factors that could affect the choice of building berth types, launching methods and facilities, with the major ones as follows:

1. Plant area and topographic characteristics
2. The coastline of the plant and its geological conditions
3. The water area of the plant and its hydrological characteristics
4. The pattern of water level change
5. Shipyard production program
6. General plan of shipbuilding process

Different launching methods have their own advantages, disadvantages, and scopes of application. When making the choice, we should consider the actual conditions, of the shipyard, and conduct serious analysis and demonstrations to choose a suitable launching method and facilities (Liu and Wang 2011).

Analysis of Ship End Launching Process

In order to prevent possible accidents, launching calculations will be carried out before ship launching, which is an important basis for building berth design, and for corresponding process measures taken during ship launching.

According to the motion state and force condition of the ship's end launching, the end launching process is usually divided into the following four stages:

1. The ship starts to slide until it contacts the water surface (shore slip).
 At this stage, the ship is only affected by gravity, the supporting force from slipway, and friction.

2. From the contact with the water surface to the start of lift by stern (launching).

The hull begins to be affected by water, with its motion direction parallel to the slipway, but it does not move in a straight line with uniform acceleration. When the moment of buoyancy to the bow pivot is equal to the moment of gravity to the bow pivot, the stern starts to float.

At this stage, it is necessary to prevent the tipping of the hull, in which the moment of the functional load to the end of the slipway is greater than the moment of buoyancy to the end of the slipway.

3. From the start of lift by stern to complete floating (lift by stern).

After the ship is lifted by stern, it continues to slide down. Since the moment of buoyancy to the bow pivot is greater than that of gravity, the hull starts to rotate longitudinally around the bow pivot while sliding. When the buoyancy is equal to the gravity of the hull, all floated point of the hull sliding is reached and the whole ship floats.

At this stage, attention should be paid to preventing the dropping phenomena, in which the fore pivot of the hull has passed the end of the slipway before the whole ship starts to float, causing the hull to drop and the bow to collide with the end of the slipway.

4. From complete floating to the ship stopping sliding (all floated).

After the whole ship starts to float, the ship continues to move forward, for about two to three times the length of the ship. Sometimes, due to the narrow waters of the shipyard, the stopping distance requirements of the ship cannot be met, so if the ship is allowed to slide freely, the launching ship may collide with other anchors and facilities in the opposite shore or in the waters.

Introduction

In the deep-sea mining system, the lifting system is responsible for transporting the ore collected by the mining robot to the surface mining ship (Shaw 1993). Already the early deep-sea mining research projects and experiences appear that the vertical riser pipe production methodology is the preferred technology for commercial deep-sea mining. Compared with the pneumatic lifting, the hydraulic lifting working process becomes less complicated with large lifting capacity and 50% or more high efficiency. It is considered as the most promising mineral lifting method.

Overview

Already the early deep-sea mining research projects and experience appear that the vertical riser pipe production methodology is the preferred technology for commercial deep-sea mining. Among the mining production methods (such as hydraulic, pneumatic, light medium, heavy medium, and bucket lifting), the riser pneumatic and the hydraulic lifting are the most commonly used ones (Hu et al. 2020). The pneumatic lifting method uses airlift pumps to inject high-pressure air into an underwater mixing chamber at a certain water depth of the riser pipe through an air tubing, the mineral slurry is lifted to the sea surface through the compressed air mixes which is less dense compared to the corresponding column and therefore is displaced upwards through the riser pipe (Doyle and Halkyard 2007). The lifting

efficiency associated with this method is typically less than 20%, which may result in expensive energy consumption. The hydraulic lifting uses one of the following lifting technologies, the clear water pump hydraulic lift or the slurry pump hydraulic lift. The clear water pump hydraulic lift uses a clear water pump installed in a seabed operation platform, the mineral particles are directly fed to the outlet end of the pump, and then lifted to the water surface through the riser pipe. Because the clear water pump and the mineral feeder both are operating in high-pressure conditions, the challenges associated with this method are the design difficulty, low efficiency, and the repair of a malfunctioned system. The slurry pump hydraulic lift conveys the mineral directly to the sea surface through a slurry pump connected in series in the riser pipe. Its working process becomes less complicated with large lifting capacity and 50% or more high efficiency. It is considered as the most promising mineral lifting method.

System Integration and Functions

System Components

A mining lifting system typically consists of a flexible pipe/jumper, a flexible pipe-lifting pump, a rigid riser pipe, and multi-stage electric lifting pumps (Qiu-Hua et al. 2019). The rigid riser pipe is connected to the mining vehicle/collector using a flexible jumper hose, which is suitable for the collector to accommodate the seafloor topography. Buoyancy materials are applied to the flexible jumper to maintain its design spatial configuration. The rigid riser pipe bottom is connected to the flexible jumper through a buffer module, which could effectively ensure the relative independence of the riser pipe system and the mining vehicle (Qiu et al. 2018).

System Functions

The integrated mining lifting system, as the core of the complete mining system, can be mainly responsible for the safety and reliability of the entire system operations. Based on the operational requirements and the features of the mining

system, the main functions of the lifting system are summarized as follows (Liu et al. 2014):

- It provides the important passage and linkage between the seabed mining system and the surface support system.
- It supports the attached power cable and controls the umbilical.
- The flexible pipe is configured to ensure the mining vehicle has enough free-moving space and effectively isolates the disturbances from mining vessels and buffer modules to the mining vehicle operation.
- The buffer module is implemented as a free-hinging container above the seabed to ensure a clogging-free continuously dosing of the riser system.

Classification of Mineral Vertical Transport Systems

Based on the lifting mechanism, mineral vertical transport systems can be divided into hydraulic lifting systems and airlift systems.

Hydraulic Lifting System

Hydraulic Lifting Principle

The mineral hydraulic lifting is conducted in the following steps: (1) the minerals collected by the mining vehicle are pumped into the buffer module through the flexible pipe; (2) the feeder in the buffer module uniformly transports the minerals to the rigid riser pipe; (3) the pressure difference inside and outside the riser pipe provided by the electric pump forms an up-flow in the riser pipe and transports the mineral particles to the surface. The electric pump needs to be designed to overcome the friction caused by the flow of the slurry, and also overcome the potential energy resulted from the density difference between the mineral slurry and the seawater. The pressure inside the riser pipe below the pump elevation is lower than the hydrostatic seawater pressure outside the riser pipe, therefore the minerals are lifted by the net pressure head of the seawater in this riser section. The pressure in the riser pipe above the pump

elevation is higher than the pressure outside the riser pipe, and thus, the minerals are transported by the pump pressure.

Main Components of the System

The key equipment components of the hydraulic lifting system include mainly the lifting electric pump, the rigid riser pipe, the flexible pipe, the flexible pipe lifting pump, the buoyancy materials, and so on.

Rigid Riser Pipe

- Material selection for the rigid riser pipe.

The materials for the rigid riser pipe should be high in strength with corrosion resistant, friction resistant, fatigue resistant, and bending resistant. Generally, the high-yield strength steel is used for the riser pipe, and other materials such as titanium alloy can be also used.

- Diameter of rigid riser pipe.

The outer diameter is mainly designed based on the following factors: the riser self-weight and the dead weight of the lower suspension equipment; the bending stress and deformation from the ship's motion or from the sea current loading. In the preliminary design phase, the riser wall thickness is determined for the static load tensile stress, and in consideration of the dynamic load amplification coefficient for heave compensation and the bending stress coefficient. From experience, in the case of moderate or rough sea state (4 or 5 WMO Sea State Code), the dynamic load amplification coefficient could be around 1.1 for heave compensation and 1.4 if there is no heave compensation, and the bending stress coefficient could be 1.2.

- Riser joint connections.

The rigid riser pipe is made up of pipe bodies and pipe joints. Currently, the oil riser casing is used for deep-sea mining pilot tests. The riser pipe joints are special threaded joints, the upper end of the riser pipe is supported by the ship using a ball joint/flex element, and the lower end is connected to the buffer module using a cross-type swing connector.

Flexible Pipe

- Function requirements.

The main requirements for the flexible pipe are: (1) The flexible pipe should have good bending flexibility/strength and radial rigidity to maintain the stability of the shape of the pipe during mining operations; (2) the flexible pipe configuration should have good flexibility to meet the mobility requirements of the mining vehicle/collector.

- Lifting method.

The flexible pipe system for subsea mining operation uses either a pressure feed type or a suction type of method. For the pressure feeding type, a pump is installed on the mining collector; during operation the pressure inside the pipe is higher than the static seawater pressure outside the pipe, and the pipe is subjected to radial pressure within its stress limit. For the suction type, a pump is installed in the buffer module. During operation, the pressure inside the pipe is lower than the seawater hydrostatic pressure outside the pipe, the wall of flexible pipe is under external pressure. The flexible pipe must be designed to resist the external pressure, which demands the flexible pipe for higher strength and better flexibility. In terms of mineral transport, the fundamental difference between the suction and the pressure type is the different requirements for the flexible pipe. From a perspective point of view, it is recommended to use the pressure feeding method. However, considering the overall layout of the mining system, use of the pressure feeding method, results the pump the installed of on the collector which could inevitably bring much difficulty to the design and operation of the collector and detrimental to the overall layout. In the suction type, although the production cost of the flexible pipe is higher and the manufacturing process is more complicated, the pump is installed on the buffer module instead of the collector which could greatly reduce the design difficulty and the manufacturing cost of the collector, and the installation of the pump on the buffer module can be also used as a counterweight.

- Spatial configuration.

The spatial configuration of the flexible pipe changes relatively to the position between the collector and the buffer module. To maintain a certain spatial configuration, the buoyant materials should be properly placed on the flexible pipe.

- Length and diameter.

To determine the length of the flexible pipe, the free movement range of the seabed collector relative to the buffer module should be considered, and to meet the heave compensation height difference requirement. The longer the flexible pipe, the larger the allowed range of the collector movement, but it also creates greater resistance to the collector, and is more difficult to maintain the flexible pipe spatial configuration.

- Flexible pipe material.

The flexible pipe should have sufficient tensile strength, and internal/external pressure resistance to satisfy the minimum bending radius requirement, having good twisting characteristics, and stay neutrally buoyant in seawater.

Buoyancy Materials The function of the buoyancy materials is to maintain the spatial configuration of the flexible pipe and to reduce the system weight in water. Theoretically, the buoyancy materials must meet the following functional requirements:

- Capable of withstanding the required external hydrostatic water pressure (for every 100 m increase in water depth, the hydrostatic pressure increases by 1 MPa), and will not have damage within the specified working water depth.
- The material should not deform beyond limited allowance during operations.
- The buoyant body can withstand certain impacts and collisions during deployment and retrieving.
- Maintain low water permeability and high bulk modulus of elasticity to ensure its stable buoyancy at high water pressures.

Airlift System

Principle of Airlift

For air lifting, compressed air is injected into the underwater riser pipe, the mineral slurry is lifted upward through the compressed air mixes which is less dense compared to the corresponding column (Pougatch and Salcudean 2008). Above the injection port of the riser pipe is a three-phase flow of mineral, air, and water mixture, below the injection port is a two-phase flow of mineral and water mixture.

Main Equipment of System

The main equipment of the airlift system includes compressors, the airlift tubing/pipe and various valves, and measurement test instruments. The compressor provides the source of power, and the airlift tubing/pipe transports the pressured air.

Local/Global Buckling and Propagation

Xinhu Zhang
School of Marine Science and Technology,
Northwestern Polytechnical University, Xi'an,
Shaanxi, China

Definition

Global buckling of a submarine pipeline, similar to Euler's buckling, refers to a sudden large displacement occurs in the sideways direction, when

Local/Global Buckling and Propagation, Fig. 1 Global buckling

Local/Global Buckling and Propagation, Fig. 2 Local buckling

it is subjected to large compressive axial force caused by high temperature and high internal pressure, as shown in Fig. 1. Global buckling damages the structural integrity of a pipeline and results in excessive bending which can lead to more catastrophic failure modes, for example, local buckling, fracture, fatigue, or even buckling propagation (Zhang and Duan 2015; DNVGL-RP-F110 2018).

Local buckling on the other hand is a gross deformation of the pipe cross section due to too high external pressure, as shown in Fig. 2. If the external pressure is larger enough, the local buckling once initiated can quickly transform the pipe cross section into a dumb-bell (or dog-bone) shape that propagates along the pipe driven by external pressure alone in a very short time (Albermani et al. 2011), which is referred to as buckling propagation, as shown in Fig. 3.

Scientific Fundamentals

Cause

Submarine pipelines are often operated with a high temperature fluid to avoid wax or hydrate

Local/Global Buckling and Propagation, Fig. 3 Buckling propagation (Netto and Kyriakides 2000)

problems. Moreover, submarine pipelines have to serve under high internal pressure condition to meet the flow assurance requirement. Both high temperature and high internal pressure result in expansion. The expansion is commonly restrained by friction between pipeline and the seabed. Compressive axial force thereby is induced in the submarine pipeline. Once the compressive axial force exceeds a certain level (critical force), global buckling occurs (Hobbs 1981).

Submarine pipelines are also often operated with high external pressure. Large compressive force is produced in the radial direction of the pipeline because of high external pressure. Under the action of large compressive force, a sudden gross deformation occurs in the section of the submarine pipeline if the section contains initial ovality, local dent, or wall thickness unevenness. For thin wall pipeline (with radius-to-thickness ratio $D/T > 30$), this gross deformation occurs in elastic range of material which is referred to as local buckling. For thick wall pipeline ($12.5 < D/t < 30$), this gross deformation occurs after material yields which is also referred to as collapse (Dyau and Kyriakides 1993).

Essential Feature

Global buckling of submarine pipelines can be classified into two types: (1) vertical buckling and (2) lateral buckling. Vertical buckling is also called upheaval buckling which refers to the global buckling occurs in vertical direction. In the same way, the lateral buckling refers to the global occurs in lateral direction (in the horizontal plane and perpendicular to the axial direction of the pipeline). Vertical buckling occurs in buried submarine pipelines and the lateral buckling occurs in unburied submarine pipelines.

The driving force for global buckling of a pipeline is the effective axial force which represents the combined action of pipe wall tension force, expansion force cause by the pressure between internal pressure and external pressure, and expansion force caused by temperature difference. Effective axial force can be calculated as follows:

$$S = S_T - EA\alpha\Delta T - (p_i A_i) \cdot (1 - 2\nu) \quad (1)$$

where S denotes the effective axial force; S_T denotes the pipeline residual lay tension; E , A , α , and ν are elasticity modulus, cross-sectional area of pipeline, thermal expansion coefficient, and Poisson's ratio, respectively; p_i and A_i denote the internal pressure and the internal bore area of the pipeline; and ΔT denotes the difference in temperature relative to the ambient temperature.

Effective axial force is a key parameter that governs the buckling response of submarine pipelines. Take the lateral buckling for example. Figure 4 shows the effective axial force prior to buckling. For simplicity, it is assumed a pipeline

with free end expansion, which is a typical assumption but not always true because of end constraints by PLETs/PLEMs. When the pipeline is started up and the temperature and pressure increase, the effective force will turn into compression. If the pipeline is totally restrained, i.e., not allowed to move axially, vertically, or laterally, the effective axial force will reach its maximum compressive force of S_0 (red dotted line). This force will vary along the pipeline as the temperature and pressure show decreasing profiles along the pipeline. Normally the pipeline ends are free to expand axially, and the effective axial force will therefore end up at zero at the ends (see the black, solid curve in Fig. 4).

Figure 5 shows the general behavior during global buckling. It is split in two, the left part shows the effective axial force, S , over a shorter section of the pipeline. This figure is before the pipeline is started up, so the effective axial force is zero (assuming zero residual lay tension as a simplification). The right part of Fig. 5 shows the typical development of the effective axial force overtime at one location in this pipeline section. For this case, the location is at a significant imperfection where a lateral buckle will be triggered when the effective axial force reach its critical value, S_{init} . Note that this critical value, which is sufficient to trigger a buckle, depends on pipeline properties, pipe soil resistance, and the imperfection. This is also illustrated in the left part of Fig. 5 with the upper hatched line giving the varying S_{init} along the pipeline section.

Figure 6 shows the compressive effective axial force, S_0 , as the temperature and pressure increase during start-up. As seen to the right, the force has

Local/Global Buckling and Propagation,

Fig. 4 Effective axial force, prior to buckling (DNVGL-RP-F110 2018)

Local/Global Buckling and Propagation,

Fig. 5 General behavior during global buckling – critical buckling force (DNVGL-RP-F110 2018)

Local/Global Buckling and Propagation,

Fig. 6 General behavior during global buckling – start-up and increase of effective axial force (DNVGL-RP-F110 2018)

Local/Global Buckling and Propagation,

Fig. 7 General behavior during global buckling – effective axial force reaches critical value and a buckle is triggered (DNVGL-RP-F110 2018)

not reached the critical value, S_{init} , and no buckling has been triggered.

In Fig. 7 the temperature and pressure have further increased, and the effective axial force has reached the critical value, S_{init} , (point A). The pipeline buckles, and the effective axial force at the apex of the buckle will drop toward the post-buckling value, S_{post} (point B). The

effective force will gradually build up away from the apex of the buckle due to the axial pipe-soil restraining force or axial friction, f , giving the slope in the effective force diagram. The axial feed-in to the buckle (indicated by the yellow arrows) will be proportional to the shaded area between the solid line and the potential effective force line.

Local/Global Buckling and Propagation,

Fig. 8 General behavior during global buckling – pressure/temperature increased further and second buckle triggered (DNVGL-RP-F110 2018)

If the pressure or temperature is further increased, a neighboring imperfection may trigger a buckle and change the effective axial force diagram as shown in Fig. 8. From this point, the post-buckling force in the apex of the buckle (point B) will remain constant, but the axial feed-in to the buckle will increase, proportionally to the shaded area. As this axial feed-in is what drives the lateral buckle, the buckle will increase in deformation as the feed-in continues.

A typical fully developed force profile for a pipeline with multiple buckles and free ends is shown in Fig. 9. At each buckle, the effective axial force reduces as the adjacent pipeline section feeds in to form the buckle. The critical buckling force for each buckle varies, depending on the initial out-of-straightness, seabed frictional response, and buckle spacing. In the feed-in parts of the buckles, the slope of the effective axial force profile is governed by the axial friction. Between adjacent buckles virtual anchors are formed at positions of zero displacement, effectively dividing the system into a series of short pipelines anchored at each end. The virtual anchor spacing (VAS) associated with each buckle varies. The response of the pipeline between virtual anchors is analogous to the response between real anchors, and the loading caused by feed-in in to the buckle is characterized by the VAS.

The probability of the initial pipeline configuration to share the available thermal expansion over several buckles or to feed into one single or fewer buckles are determined by the initial pipeline configuration and the pipe-soil interaction parameters.

Local/Global Buckling and Propagation,
Fig. 9 General behavior during global buckling – final configuration with multiple buckles (DNVGL-RP-F110 2018)

Critical buckling pressure is a key parameter that governs the local buckling response as well as buckling propagation of submarine pipelines.

Figure 10 shows a typical response of local buckling and buckling propagation. As seen to the left, the total volumetric change rate increases linearly as the external pressure increase. When the external pressure reaches a certain level is referred to as critical buckling pressure, a gross deformation occurs. The certain value is called critical buckling pressure. After that, total volumetric change rate increases rapidly, whereas the external pressure decreases. When the external pressure drops to certain level, the local buckling propagation is trigger and the local buckling propagates swiftly along the pipeline, as seen to the right in Fig. 10. The certain value is called buckling propagation pressure. The critical buckling pressure and buckling propagation buckling

Local/Global Buckling and Propagation, Fig. 10 A typical response of local buckling and buckling propagation for submarine pipelines

pressure are two key parameters for the design of submarine pipelines.

Key Influence Factors

The two primary factors that affect the global buckling response of submarine pipelines are initial imperfections and pipe-soil interaction.

The initial imperfections may be caused by uneven seabed, crossing arrangement, curvature in the horizontal plane purposely made or randomly imposed during installation, or engineered initiators such as sleepers or increased buoyancy. The initial imperfections are described by three parameters. The initial imperfection amplitude, wavelength, and shape are three primary parameters to describe the initial imperfection of a submarine pipeline. The global buckling is greatly affected by these three parameters as well. This point has been verified by many studies (Taylor and Gan 1986; Taylor and Tran 1993; Karampour et al. 2013; Zeng et al. 2014). The initial imperfection amplitude and wavelength are quite clear, and they have specific physical meanings. However, the initial imperfection shape is an unclear and unquantifiable parameter. A characteristic parameter of initial imperfection shape was

found by Zhang and Duan (2015) which can be quantified and can represent the effect of initial imperfection shape on the global buckling response. The characteristic parameter is the ratio of maximum curvature radius to the initial wavelength. This conclusion has been confirmed by Karampour (2018) and Chee et al. (2018). By now the effect of initial imperfections on the critical force of global buckling has been unified, as follows:

$$S_{\text{int}} = g(w_0/L_0, \rho_{\text{max}}/L_0)(EIq^2)^{1/3} \quad (2)$$

where EI denotes the flexural stiffness of the pipeline; q denotes the vertical load; w_0 and L_0 denote the initial imperfection amplitude and wavelength, respectively; ρ_{max} denotes the maximum curvature radius; and g is a coefficient function which represents the effect of initial imperfections on the critical of global buckling.

Global buckling behavior of exposed and buried pipelines is strongly linked to the pipe-soil interaction. The pipe-soil interaction includes vertical pipe-soil interaction, axial pipe-soil interaction, and lateral pipe-soil interaction. Vertical pipe-soil interaction is of major concern for

upheaval buckling, as it affects the mobilization load. Upward resistance and downward stiffness are two important parameters that influence the vertical pipe-soil interaction. A multi-linear model is normally used to describe the vertical pipe-soil interaction (Schaminee et al. 1990; Palmer et al. 2003; White et al. 2008).

The axial pipe-soil interaction is relevant when any buckling mode is triggered as it affects the post-buckling configuration. The axial feed-in from the straight sections into the buckled region is determined by the mobilized axial reaction. The axial pipe-soil interaction is also important for the axial force build-up, either during buckle development, at the pipeline ends or after a buckle has occurred. A high axial breakout resistance will influence the global buckling initiation, but to ensure conservatism in the design process, this is generally not accounted for. Therefore, residual axial resistance should be used to model thermal expansion and post-buckling behavior. A bilinear model is normally used to describe the axial pipe-soil interaction unless the real data for axial pipe-soil interaction is acquired.

For an exposed pipeline free to buckle laterally, the lateral pipe-soil interaction is one of the key parameters as it influences both the critical buckling load (breakout resistance) and pipeline post-buckling configuration (residual soil resistance after breakout). The lateral pipe-soil resistance is also the key parameter for the lateral buckling on even seabed as it influences both mobilization load (breakout resistance) and pipeline post-buckling configuration. At mobilization, when the pipeline starts to deflect laterally and the displacements are small, the lateral soil resistance is governed by the breakout value. For increasing lateral displacements, the lateral soil resistance may decrease to a lower residual value. In the tail of the buckle, where little lateral movement occurs, the lateral resistance will always be the breakout resistance, and this will influence the post-buckling configuration. A tri-linear model is normally used to describe the lateral pipe-soil interaction (White and Cheuk 2008).

The critical buckling pressure for submarine pipelines is primarily affected by diameter-to-

thickness ratio, elastic modulus and yield stress of material, initial imperfections, and corrosions.

For thin wall pipeline, the critical buckling pressure can be determined by the classic formula (Timoshenko and Gere 1961), as follows:

$$P_c = \frac{2E}{1-\nu^2} \left(\frac{t}{D} \right)^3 \quad (3)$$

For thin wall pipeline, the critical buckling pressure can be determined by experience formula (He et al. 2014), as follows:

$$\frac{P_c}{P_y} = -1.478 \left(\frac{D}{t} \right)^{0.611} \left(\frac{\sigma_y \cdot S}{E} \right)^{0.379} + 2.436 \left(\frac{D}{t} \right)^{-0.094} f_0^{-0.047} \left(\frac{\sigma_y \cdot S}{E} \right)^{0.049} \quad (4)$$

where σ_y is the yield stress of material, and P_y is yield pressure which can be determined by:

$$P_y = 2\sigma_y \frac{t}{D} \quad (5)$$

and S is a parameter describing the anisotropic yielding. It is defined as:

$$S = \frac{\sigma_{ya}}{\sigma_{yc}} \quad (6)$$

Where σ_{ya} and σ_{yc} denote the yield stress in the axial and circumferential directions, respectively.

The elastic modulus and yields stress of material are acquired by material experimental tests. The Ramberg-Osgood model is often used to represent the material constitutive relation (stress-strain curve). It is defined as follows:

$$\varepsilon = \frac{\sigma}{E} \left[1 + \frac{3}{7} \left(\frac{\sigma}{\sigma_y} \right)^n \right] \quad (7)$$

where n denotes the hardening parameter which can be determined by material experimental tests.

Initial imperfection existed in the submarine pipelines in the form of ovality, wall thickness

unevenness, corrosion, or local dent. The ovality describes the out-of-roundness of cross section of a pipeline which is induced during the manufacture of the pipeline and can be measured by:

$$\Delta_0 = \frac{D_{\max} - D_{\min}}{D_{\max} + D_{\min}} \quad (8)$$

where $D_{\max}$ and $D_{\min}$ denote the maximum and minimum diameter of the pipeline. Similarly, the wall thickness unevenness describes the wall thickness variations of a pipeline which is also induced during the manufacture of the pipeline and can be measured by:

$$\Xi_0 = \frac{t_{\max} - t_{\min}}{t_{\max} + t_{\min}} \quad (9)$$

where $t_{\max}$ and $t_{\min}$ denote the maximum and minimum wall thickness of the pipeline.

The loss of metal in a pipeline due to corrosion usually results in localized pits with various depths and irregular shapes on its external and internal surfaces which has a great influence on the critical buckling pressure. Details on this, please see Fatt (1999), Netto et al. (2007), Sakakibara et al. (2008), Netto (2010), and so on.

The buckling propagation pressure for submarine pipelines is primarily affected by diameter-to-thickness ratio and yield stress of material. It can be calculated by the classic result (Palmer and Martin 1975):

$$P_p = \frac{\pi}{4} \sigma_y \left(\frac{t}{r} \right)^2 \quad (10)$$

where P_p is the propagation pressure and t is the radius of the pipeline. Some modifications were made by previous studies (Kyriakides and Babcock 1981; Albermani et al. 2011; Gong et al. 2012).

Engineering Measurements

The structural integrity of a pipeline susceptible to global buckling can be assured by two different design concepts: (1) restraining the pipeline with the high compressive forces (buried pipelines) and (2) allowing the pipeline to buckle globally and thereby releasing the expansion forces (exposed/unburied pipelines).

For vertical buckling, burial is the most common method to prevent pipeline buckling. Trenching and backfilling, rock dumping are two primary methods to bury a pipeline against the vertical buckling.

For lateral buckling, snake-lay (Fig. 11), vertical upset (Fig. 12), and distributed buoyancy (Fig. 13) are three primary methods to control the lateral buckling. The critical axial force of lateral buckling for the submarine pipeline is decreased by these ways. Therefore, the lateral buckling is easy to trigger and the expansion forces are released by controlling the formation of lateral buckles along the pipeline. The buckled pipeline can withstand more compressive axial force. The uncontrolled lateral buckling becomes

Local/Global Buckling and Propagation, Fig. 11 Typical snake-lay configuration (Bruton et al. 2005)

Local/Global Buckling and Propagation,

Fig. 12 Buckle initiation using distributed buoyancy (Bruton et al. 2005)

Local/Global Buckling and Propagation,

Fig. 13 Buckle initiation using sleepers (Bruton et al. 2005)

Local/Global Buckling and Propagation,

Fig. 14 Buckling arrestor (Netto and Kyriakides 2000)

controlled. More details please see Harrison et al. (2003), Bruton et al. (2005).

The buckling propagation can be controlled by installing buckle arrestors, at intervals along the pipeline, Fig. 14. The purpose is to limit the extent of damage to the pipeline by arresting the collapse propagation. Buckle arrestors are devices that locally increase the bending stiffness of the pipe in the circumferential direction, and therefore they provide an obstacle in the path of the propagating buckle. More details please see Toscano et al. (2008).

Definition

The underwater acoustic positioning system that is used to track underwater vehicles and divers can be divided into a **long baseline LBL (Long Baseline)**, a short baseline SBL (Short Baseline), and

an ultra-short baseline USBL or SSBL (Ultra-Short Baseline/Super Short Baseline) system according to the array spacing. The length of the long baseline underwater acoustic positioning array is generally 100–6000 m. It is arranged on the seabed according to a certain geometric shape. The adjacent three or four array elements form a matrix, which is used to measure the underwater target sound source to each element. Distance determines the location of the target. With the development of underwater acoustic localization technology, distributed underwater acoustic localization technology has become a research hotspot in recent years. Its baseline length is longer, up to tens of kilometers. It uses underwater submerged nodes as positioning beacon arrays. Its form and function are very similar to underwater communication networks (Vickery 1998).

At present, the long-baseline underwater acoustic localization technology is relatively mature. Because of its long range and high positioning accuracy, it has a wide range of applications in underwater shooting range, underwater construction, submarine cable laying, offshore oil exploration, and marine geological monitoring. At the same time, the long-baseline positioning technology system is complicated, the system is difficult to deploy and recycle, and the untimely factors such as the time-consuming array of the array are limited, which limits the application in some scenarios.

System Structure

The long baseline underwater acoustic positioning system consists of a question and answer (transceiver) and a transponder (beacon). The transceiver is usually installed on the target to be measured, such as surface ships, submarines, torpedoes, UUVs. When positioning and navigating the target to be measured, multiple transponders are required to form a transponder array, and the measured target motion is generally located in the array.

There are three methods for measuring the array of underwater beacon arrays, such as absolute array, relative array, and joint array. The absolute array is to calibrate the beacons one by one or

multiple standard groups. Generally, the mother ship uses the range finder to draw a single beacon, and the distance measurement and the angle sensor are used to correct the ranging and angle information. The baseline solution mode solves the beacon coordinate position. This kind of traditional absolute array technology reduces the calibration efficiency with the increase of depth in the deep sea operation, which takes a lot of time, and is greatly affected by the sea state, the mother ship track, and the sound velocity distribution, and it is difficult to obtain high-precision calibration results. With the development of software and hardware technology, beacons have a variety of functions such as range, communication and the development of relative array technology, which uses the long baseline principle to measure the distance between beacons, and finally uploads by the surface unit. The information is solved to obtain the relative formation, and then the ship's position information is used to obtain the geodetic coordinates of the formation (Zhang et al. 2016; Larsen 2000). Because the underwater environment is stable, the beacon is relatively stationary, and the difference in sound velocity changes is small, so the time is less, and the accuracy of the obtained array information is higher. The joint array technology combines the absolute array and the relative array technique. The principle is to calculate the absolute position coordinates of the matrix based on the relative position coordinates of the beacon and the absolute position coordinates of any two beacons.

Both underwater beacons and buoys can act as a matrix of transponders. When the beacon array is formed by the beacon on the seabed, the target to be measured may be an underwater or water surface target, and the system is constructed as shown in Fig. 1. When the array is fixed, the beacon is fixed or anchored to the seabed. If the system is not used for a long time, an acoustic release device can be added between the beacon and the anchor. When working, the question answering machine on the target to be tested first sends an inquiry signal, and the beacon in the underwater beacon array sends back a response signal after receiving the signal, and each beacon response signal is on a different channel. The time taken by the measured target from the issuance of

Long Baseline Underwater Acoustic Location Technology, Fig. 1 Beacon response array system composition diagram

Long Baseline Underwater Acoustic Location Technology, Fig. 2 Buoy response array system composition diagram

the interrogation signal to the receipt of the response signal of the beacon is twice the acoustic propagation time between them, so the relative coordinates between the measured target and the beacon can be calculated. Since the beacon is placed and positionally calibrated, the geographical coordinates are determined, so that the trajectory of the measured object relative to the earth during continuous motion can be further obtained.

For the long baseline buoy positioning system, as shown in Fig. 2, the underwater beacon is replaced by a radio buoy on the sea surface, and the underwater target is equipped with synchronous or asynchronous beacons. When the beacon (sound source) and the buoy (measurement system) on the target are equipped with a high-

precision synchronous clock system, the satellite navigation and positioning system such as GPS is generally used to perform timing and correction on the device, that is, between devices in the system. There is a timing error, and the system formed at this time is called asynchronous positioning system, otherwise, it is called an asynchronous positioning system. The buoy is composed of a building block. The top of the support bar on the water is a wireless communication antenna, a positioning device (GPS/BD) antenna and a beacon light. The lower end is equipped with a floating body to provide buoyancy and then connected down to the electronic compartment. The battery is installed in the cabin, radio stations, positioning, attitude measurement and other equipment,

hydrophones, transducers, and other equipment installed below the electronic compartment.

The communication base station installed on the work ship serves as the central station of the radio station. The data such as hydrophone, sensor, and positioning information are uniformly packaged by the radio buoy and transmitted to the work ship. At the same time, the work ship is equipped with display and control equipment (table). Solve the positioning position of the underwater target. If there is a data confidentiality requirement, the wireless transmission data can be encrypted.

In the specific use of the long baseline positioning system, depending on the actual application and application, the system configuration sometimes uses the underwater beacon array and the surface buoy array.

Positioning Principle

The measurement of the azimuth and distance (or distance difference) is performed by using the pulse signal transmitted by the measured object to arrive at each array element delay (or delay difference) information. The long

baseline system positioning solution method has multiple solution models, and the classical and representative spherical intersection method and hyperbolic intersection method are compared. Synchronous system solutions generally use a spherical intersection model, and nonsynchronous system solutions generally use a hyperbolic intersection model.

As shown in Fig. 3, where the coordinates of the i -th buoy is $P(x_i, y_i, z_i)$, the measured target position to be solved $S(x_s, y_s, z_s)$, which is determined by measuring the propagation delay of the measured object to each buoy. The distance from the target to each buoy, that is, the slant distance between $P(x_i, y_i, z_i)$ and $S(x_s, y_s, z_s)$, solves the target position by geometric intersection. For a single buoy, the propagation delay determines the spherical surface on which the sound source is located, and the spherical equation determined by the i -th buoy is

$$\begin{aligned} (x_i - x_s)^2 + (y_i - y_s)^2 + (z_i - z_s)^2 \\ = c^2(\tau_i - \tau_b)^2 \end{aligned} \quad (1)$$

where τ_i is the propagation delay of the i -th buoy from the target measured by the system; τ_b is the

Long Baseline Underwater Acoustic Location Technology,
Fig. 3 Long baseline positioning system working principle diagram

delay difference between the signal transmission time of the target (beacon) source and the measurement system (buoy) clock; c is the speed at which sound waves travel in water.

For the synchronous positioning system, the formula (1) becomes the following formula (2)

$$(x_i - x_s)^2 + (y_i - y_s)^2 + (z_i - z_s)^2 = C^2 \tau_b^2 \quad (2)$$

According to the geometric principle, the two spherical surfaces intersect in one circle, and the three spherical surfaces are compared with two points. The intersection of the four spherical surfaces can determine the only point in the space. In general, the target value z_s is known because the target is installed with a depth sensor, and the “spherical intersection model” of Eq. (2) will be transformed into the “circle intersection model.” The two circles intersect at two points (one point when tangent), and if there is a third circle equation, a unique point on the plane can be determined. Therefore, in the case where the depth is unknown, four buoy array elements are needed, and in the case where the depth is known, only three buoy array elements are needed to solve the unique target solution.

For the nonsynchronous positioning system $\tau_b \neq 0$, if it is an unknown number, if the spherical intersection model is still used, a large positioning error will be generated. Although the absolute delay of the measured target to each buoy cannot be known, the delay difference between the measured target and each buoy is a fixed value. According to the analytic geometry, the distance to the two focal points is a fixed value, and the corresponding quadratic equation can determine a hyperboloid. Therefore, the nonsynchronous positioning system solving model is called a “hyperbolic intersection model.” If the measured target depth is unknown, the positive value of the two sets of solutions is the measured target position. When the measured target depth is known, the three array elements can determine the target position double solution. If the double solution is a positive number, the unique solution is obtained by the redundant array element (Janik 2005; Baccou et al. 2001).

Application and Development Trends

The long-term baseline positioning methodology has developed earlier, forming a mature industry, and the products have been serialized. The history of the first long-baseline system can be traced back to 1958. The Applied Physics Laboratory of the University of Washington in the United States built a three-dimensional coordinate tracking underwater shooting range in Dabo Bay, using four transponders placed on the seabed to achieve continuous underwater targets tracking. At present, well-known companies engaged in long-term baseline positioning abroad include French iXblue, Norwegian Kongsberg, and British Sonardyne. In fact, the above companies are involved in the long baseline, short baseline, and ultra-short baseline positioning, as well as some companies specializing in the development of long baseline positioning systems, Benthos, SonarTech, ORCA, etc.

iXblue has a strong technology and R&D team, and its positioning products can combine INS, DVL, GPS, and other equipment to form a comprehensive underwater navigation system. RAMSES is an Acoustic Synthetic Baseline (ASBL) positioning system that makes long-baseline and sparse long baseline (Sparse LBL) positioning easier. The system combines inertial navigation systems to improve positioning with significantly reduced transponder usage. Accuracy and system robustness, the system operating frequency is intermediate frequency and can provide better positioning accuracy than 0.1 m within 4000 m distance. Canopus is the new, most advanced smart transponder. The system's pressure, temperature, and tilt sensors collect environmental information, and the Embedded User Interface allows users to connect to devices using WIFI. The system has three working modes, long baseline positioning, ASBL sparse long baseline positioning and underwater acoustic data telemetry, and Modem functions, and is compatible with third-party acoustic systems, which is a development trend of the foreign acoustic industry. Kongsberg has a number of mature products in the military and civilian fields. The cPAP series transceiver is a high-precision long-baseline positioning system

developed for ROV and cable carriers. It can be connected to the acoustic positioning computer APC or the acoustic positioning console APOS through the data interface. The cPAP series includes an intermediate frequency cPAP 34 and a low frequency cPAP 17, with a maximum working depth of 4000 and 7000 m, respectively. In 2015, the new HiPAP series was introduced to achieve independent array calibration. The new Cymbal protocol applies direct sequence spread spectrum (DSSS) wideband signal processing technology to positioning and communication. HiPAP supports long baseline, short baseline positioning, and multiuser long baseline system (MULBL) mode. Single transponders work in short baseline mode; when working in long baseline mode, at least three transponders are required on the seafloor, typically four to six transponders; multiuser long baseline mode is available. The same beacon array provides positioning for multiple users including ships, ROVs, etc., in the area. Sonardyne has developed a series of long baseline positioning systems, such as the Prospector series, Dunker6 series, Fusion 6G series, and ROVNav series (Zhang et al. 2019). The sixth generation of broadband signal technology claims to provide an unlimited number of users within its system coverage (Sun and Zheng 2015).

With the continuous advancement of hardware, software technology, and the demand for industrial applications, the long baseline underwater acoustic positioning system shows some common development trends (Yang et al. 2006; Sun et al. 2012; Takasu and Yasuda 2010; Sun et al. 2019).

1. The signal system develops from narrowband to broadband, which has higher gain than conventional single-frequency signal processing and stronger antinoise capability.
2. Multisystem combined positioning, the system is not simply a long baseline system, combined with short baseline, ultra-short baseline, forming LBL/SBL, LBL/USBL, LBL/SBL/USBL combined positioning system.
3. Multifunctional integration, in addition to long baseline positioning function, integrated underwater acoustic communication, environmental parameter measurement, and other functions.
4. Multisensors are used in combination, integrating INS/IMU, DVL, etc., in the underwater acoustic positioning system, positioning and solving the data of the fusion multisensor system, greatly improving the positioning ability and accuracy.
5. Multitarget positioning, which can be developed by locating a single target from a single target, and even providing a positioning navigation service to an unlimited number of targets in the coverage area.
6. Strengthen the processing of positioning data, and apply techniques such as least squares estimation and Kalman filtering to improve the quality of positioning data.
7. Convenient operation, the system can automatically calibrate and calibrate the underwater array of water surface, even without calibration, reduce the operating cost, so that users have more energy to focus on the positioning service requirements.

Definition

Aged or severe damaged vessels or offshore structures are decommissioned or cut into several parts.

Due to some inescapable factors, such as low value, high pollution, radioactive nuclear waste, hard to divide, harmful to people, etc., the structures could not be modified for reuse nor dismantled into components. Hence, the whole structure would be stored at a place for a long period, say usually 10 years or more, waiting for the further processing.

Scientific Fundamentals

Background and Introduction

The oil and gas sector is facing a sharp rise in decommissioning spending, forecasting an increase from around US\$ 2.4 billion in 2015 to almost US\$ 13 billion, per year, by 2040 (Correa and Russel 2017). While in China, there will have 81 decommissioning oil fields, 164 offshore platforms, 3240 km pipelines, and 2310 subsea wells by the end of 2040. From this aspect, it is a great market of dismantling offshore platforms all over the world. It is necessary to rapidly develop the technologies and facilities for decommissioning offshore oil and gas platforms.

The decommissioning process provides an opportunity for financial gains due to the increased resources available for environmental and socio-economic benefits (Sudaia et al. 2018). Briefly, the decommissioning procedure consists of transporting the platform to an onshore dock, where it is dismantled and the parts removed for future sale and reuse (Dexter and Ghorashi 2016; Junior Alves and Souza 2017; Rouse et al. 2018).

Comparing with the onshore structures and pipelines, the issues of decommissioning offshore ones is much more complex. It is not only limited by the domestic and international laws or rules, the cost of decommissioning an offshore structure is more expensive than an onshore one. Besides, for some high pollution or special functional offshore platforms, when they are at the end of their life, they can hardly be exploded and removed directly. Otherwise, severe environmental catastrophe will take place. One possible approach is to tow or transport the whole structure or the divided parts to a certain place, say storage yard, and store them for a long-term period, waiting for the further processing, such

as modification, potential buyer, deep decommissioning, etc.

Before the structures are stored in place, they should be carefully evaluated whether they are valued to be long-term storage. Among different assessments, the potentiality of those retired structures are one of the key factors, and it is also the first step of the old engineering structures recycling. A reasonable determination will directly lead to the benefits in society, economy, environment, and so on.

For those structures or facilities that are being long-term stored, they will be further modified or used on other places. In other words, they are waiting for reusing or recycling. According to previous successful experiences, we found that core of the structure recycling is that they are easy to be constructed. At the beginning stage of decommissioning, due to the usage of the structure is not in decision, the potentiality will determine the chance of its future reuse. Moreover, during the recycling project, the constriction conditions, including the difficulties in modification, costs, and so on, will also affect the final determination.

According to previous investigations, we know that the potential recycling abilities of decommissioning structures should be determined by the following five factors, including geographical position, constriction condition, culture, economic value, and environmental adaptability. These factors are also the key elements on the judgment whether a decommissioning structure could be long-term storage until it is reused in somewhere.

Among various evaluation approaches, the TOPSIS (Technique for Order Preference by Similarity to an Ideal Solution) approach has become one of the most commonly used way to assess potentiality of the retired structures. Although TOPSIS theory is firstly proposed by C. L. Hwang and K. Yoon in 1981, it is still a classic method to estimate the relative superior of the objects. It can obtain the similarity between each alternative and the ideal solution by calculating the weighted Euclidean distance between each alternative and the positive and negative ideal solution, to serve as the criteria for prioritizing the risk level of FMEA failure modes (Liu et al. 2015).

Another potential issue during the long-term storage is the influence on the onshore and

offshore environment. Taking concrete structure as an example, after its decommissioning the structure will be divided into several parts as well as dust or wastes. It is obvious that not all of the decommissioned structured could be reused directly. Hereby, they need to be stored in somewhere and wait for the following command, and others will be buried or further proceeded. However, there may exist some harmful materials to the environment.

On one hand, comparing with the soils on earth, the decommissioned structure sometimes contains heavy metal; such as plumbum or zinc; total organic and inorganic carbon, which may have potential environmental risks for the soil; underground and surface water. On the other hand, there exists a majority of calcium silicate hydrate and calcium carbonate hydrate. If the storage scenarios are wet enough, these compounds will induce strongly alkaline leachate, which pH value is larger than 11. These will undoubtedly pollute the environment.

Therefore, the storage facilities for those potentially contaminative structures should be designed carefully. Two major principles should be obeyed, which are safety and economy, respectively. In fact, the safety factor is the basic principle. From the aspect of avoiding pollution, the storage place should have least effects on the external environment during its construction and operation. This will help to protect the atmosphere, soil, and surface and ground water from pollution. Besides, the economic factor will ensure the storage cost in a relative low level. Hereby, different elements, including site selection, capacity, transportation distance, and so on, need to be taken into consideration simultaneously.

The long-term storage of decommissioned structures can be managed according to classic management modes. Usually these modes consist of three types, which are public owned-private management (POPM), public-private partnership management (PPPM), and franchising management (FM). The differences between these managements are listed in Table 1.

The POPM mode is that the facilities are invested and established by the government. Then they are outsourced to the private or other companies to operate and maintain. That is to say,

Long-Term Storage, Table 1 Long-term storage management

Type		Property	Operation maintenance	Investment	Commercial risk
POPM	Service contract	Public	Both	Public	Public
	Management contract	Public	Private	Public	Public
	Leasing contract	Public	Private	Public	Private
PPPM	Property selling	Both	Both	Both	Both
	Quasi-BOT	Both	Both	Both	Both
FM	BTO	Private-government	Private	Private	Both
	BOT	Private-government	Private (during contract)	Private	Private (during contract)
	TOT	Government-private-government	Private (during contract)	Public	Private (during contract)

the property belongs to the government, while the management right is attributed to the companies. Specifically, it contains three major approaches, which are service contract, management contract, and leasing contract, respectively.

The PPPM mode is that a new company is established by both private company and government. Based on the investment ratio, the commercial risks and profits are both proportionately shared. There usually are two types in this mode, property selling and quasi-BOT mode.

The FM mode is that the major part or all of the investment are provided by the private company. According to specific cooperation ways, the company and government will share the risks and profits. Based on the actual income of the projects, the government will collect the operating expenses/compensate the loss from/to the company. However, because the final ownership belongs to the government, there exists a progress of the ownership and management right transformation. Specifically, there are three major types, including build-transfer-operate (BTO), build-operate-transfer (BOT), and transfer-operate-transfer (TOT) modes.

Key Applications

Long-Term Storage for Normal Offshore Structure Wastes

For normal decommissioning offshore structures, most of the demolished components are hardly

used in the present stage. In other words, they could be classified into structure waste. These structure wastes have the following characteristics, including large in amount, huge variety, high pollution, etc. Besides the giant cost to proceed these wastes, it will also require a big place to store them before they are proceeded or recycled. Therefore, it has induced a series of issues in both environment and society. Moreover, with the development of society, more and more aged offshore structures will be abandoned, which, hereby, will cause a much more severe problem in the future.

Actually, some of the offshore structure decommissioning wastes could be recycled after some working procedure, even though a small part of them cannot be easily handled with current technology. Hereby, some processing experiences of onshore structures decommissioning wastes could be referred.

Taking Shanghai 2010 EXPO construction as an example, based on its construction progress, the decommissioning projects are flexibly adjusted. In order to balance the wastes produced by decommissioning and the requirements from construction, the decommission plan will be adjusted in real time. The committee designed a temporary storage place to arrange the structure wastes. Its main function is buffer and information feedback. When the waste production exceeds the requirement of the construction, the waste will be transported to the storage place, waiting for the

following commands. However, the storage place is area-limited. Thus, when the stored wastes reach threshold, the information will be sent to the executive center, and the decommissioning plan will be adjusted to reduce the waste generation.

We believe that such approach also has significant guidance to the offshore structures' decommissioning and long-term storage. It is possible to adopt this in-time adjusting approach in the offshore structures decommission and constructions in the shipyards. However, it should be noted that this method may not be available for the offshore installations, as the installation cost is in very high level.

Long-Term Storage for Radioactive or Other Polluting Offshore Structure Wastes

Apart from the common wastes of the decommissioning offshore structures, such as concrete, steel, jacket pipe, etc., there are also

some radioactive components in the offshore structures, like floating nuclear plant (FNP) and nuclear power ship. Although their design lives are usually more than 40 years, it will undoubtedly retire in the future. As a special type of energy supplier, nuclear fuel provides a lot of benefit for our life as well as the offshore structures. However, how to proceed its waste has become a worldwide issue.

The 70 MW Akademik Lomonosov Floating Nuclear Co-generation Plant (the first FNP all over the world, see Fig. 1) was established since 2007, and it was towing to its operation area in August 2019. There are two nuclear reactors in this FNP. Each reactor is enclosed in a steel hermetic containment vessel to withstand the pressure. It will have a lifespan of 40 years.

After its lifetime ends, the FNP cannot be easily decommissioned, especially the nuclear cores.

Long-Term Storage, Fig. 1 Floating nuclear co-generation plant. (Source: www.rosatom.ru)

Nuclear decommissioning is the final technical and administrative process in the life cycle of nuclear power operation. As such, decommissioning must strive to ensure public safety. This goal requires many factors be involved in the decision-making process (Suh et al. 2018). Typically, a 40–100 years of storage are usually involved in storage strategy. Most of the wastes are long-term stored in dry casks at various locations (Yano et al. 2018). Licenses for the storage of spent nuclear fuel (SNF) and vitrified highly active waste in casks under dry conditions are limited to 40 years and have to be renewed for prolonged storage periods (Gerold 2018).

At present, the United States does not have a designated disposal site for used nuclear fuel – the nation therefore faces the prospect of extended long-term storage (i.e., >60 years) and deferred transportation of used fuel at operating and decommissioned nuclear power plant sites (Chopra et al. 2014). An investigation on poly-ether ether ketone (PEEK) composite for long-term storage of nuclear waste highlights the effect of radiation and chemical and thermal environments on mechanical and thermal properties of PEEK and presents which of these materials could be an alternative material for long term storage of nuclear (Ajeesh et al. 2015). The results they have obtained are shown as follows: (1) the dispersion of carbon short fiber in the PEEK Composites is significantly uniform from the study under optical microscopy; (2) there are no significant changes in thermal properties of PEEK composite when exposed to aggressive environments from differential scanning calorimeter (DSC) and thermo gravimetric analysis (TGA). As a result, to determine the storage period and material could be the key problem of long-term storage of nuclear waste with offshore structure.

Fatigue Problem During Long-Term Storage

Long-term fatigue assessment of an offshore structure is a challenging practical problem, no matter during its working or storage periods. Various efficient strategies have been proposed in the literature; however, they generally suffer from one or more shortcomings. Low (2016) proposed a new analysis approach, based on using the

classical control variates technique to improve the efficiency of Monte Carlo simulation (MCS). According to his case study, the results show that substantial reduction in the sampling variability of MCS are provided. Time domain simulation is another common method to predict the long-term fatigue damage in offshore engineering. Taking the high-pressure hydraulic power take-off (PTO) machinery in a heaving-buoy wave energy converter (WEC) as example, Yang and Moan (2013) presented the fatigue analysis with time domain simulation. They obtained long-term pressure loads by combining the short-term time simulation results and the occurrence probability of each sea state. Two models (Weibull and generalized Gamma distributions) were applied to fit the long-term rain flow-counted pressure cycles.

Corrosion Problem During Long-Term Storage

Corrosion problem is one of the significant issues during the offshore structure operation, due to the wet and salty ocean environment. During its lifespan, there are some approaches, such as sacrificial anode, polymer anticorrosive material, duty paint, etc., to solve or relieve this slow chemical reaction. However, during the long-term storage, the corrosion protection should be paid attention to, as most of the protection terms are out of work. If severe corrosion occurs on the storage structures, it will clearly affect the following reuse.

Moreover, there is a potential way to store the decommissioned offshore structures in some underground area, if it is not against local law. Subsurface developments have many potential uses ranging from defense installations to transport and retail outlets. Besides, it has great potential ability for the storage. If this storage is adopted, the corrosion issue will be more critical to the structures. Gschwandtner and Galler (2018) assessed the stability of underground structures during a long-time behavior. According to their investigation, geotechnical engineering and geology, hydrogeology in particular, show great influences on the behavior of structure and surface area. They conducted a four-year-length survey, as well as a numerical simulation, to perform the

study. Their results show that the influence of underground and surface waters, especially for those areas that are sensitive to water, cannot be neglected in the consideration of long-term stability.

Brilliance of the Seas; Luxurious cruise ship; Luxury passenger liner

Definition

Luxury cruise is regarded as the “mobile palace in the sea” (Yin 2012), which is the high-valued equipment for the tourism industry. It provides tourists with unforgettable sailing experiences and incredible enjoyment through its different types of facilities.

Scientific Fundamentals

Development History

In the late nineteenth century and the early twentieth century, people traveled across the sea only by cruise ships, which just provided passengers with limited rooms and food services. With the increasing maturity of aircraft technology, in order to save time and money, many passengers choose to travel by airplane. Therefore, in the middle of the twentieth century, the cruise ship industry declined. In order to survive, cruise companies developed the concept of cruise vacation (Duman and Mattila 2005), which transformed the transport-oriented cruise ship into a marine holiday village and built the cruise ship with more luxurious facilities, more programs, and larger displacement. Therefore, luxury cruise has been gradually more and more flourishing since the 1980s (Shan et al. 2017) and has become an independent part of the world tourism industry.

Structural Features

As a typical representative of the high-end product of manufacturing industry, the luxury cruise has integrated the features of advanced manufacturing with the concept of modern services, sightseeing, tourism, and entertainments. The luxury cruise is totally different from mainstream ships in design concept, construction technology, operation, management, and other aspects, which directly reflect the scientific and technological level and comprehensive industrial ability of a country. Compared with the conventional ships, luxury cruise has the following characteristics (Luo and Gan 2017):

1. The molded breadth is relatively large, while the molded depth, relatively small.
2. Double bottom, double hull, long superstructure, square stern, curved nose bow, and underwater bulb.
3. There are many water-tight compartments in the main ship, all of which are plane bulkheads. The deck, board side, and bottom are longitudinal structures. The framework is mostly constructed by flat bulb steel.
4. The superstructure is divided according to its functions, and the public entertainment place is spacious with few pillars.
5. The visible structure focuses on coordination and beauty. The upper and lower structures are designed to be aligned.
6. The high requirements of vibration control and noise elimination.
7. The type of rooms in the luxury cruise involves standard room, sea-view room, superior royal suite, and so on. For the specialty in comfort and function, the structural type and layout in rooms are also different (Fig. 1).

Difficulties in the Structural Design of Luxury Cruise

The structural design of luxury cruise should not only meet the intensity requirements of classification regulations but also comply with its mission of providing high-end services to tourists. The design difficulties can be summarized as follows:

Luxury Cruises, Fig. 1 Basic structure of luxury cruise (<http://image.baidu.com/>)

Plate Welding Distortion Control

High-strength steel has been widely used in shipbuilding. Its beneficial effect is to reduce the weight of the structure and improve the navigation performance and energy efficiency of ships. However, it also brought some negative effects, one of which was that as the thickness of the plate decreased, the welding deformation increased. The thickness of the hull structure of a luxury cruise should be relatively small, especially for superstructures and deck compartments. Most of the plate thicknesses can be among 5–6 mm. Large welding distortions above the waterline seriously affect the aesthetics of the hull, while larger welding distortions below the waterline will not only affect the navigation performance of the vessel but also reduce the ability of the vessel's external plating to withstand the effects of water pressure. The exterior appearance of the luxury cruise ship needs to be aesthetically pleasing. Therefore, the exterior surface of the ship must not exhibit any aesthetic welding distortion.

Vibration and Noise Control

Tourists take a luxury cruise tour to have the relaxing and enjoyable life. However, ship noise can not only influence the normal navigation of the ship but also reduce the comfort of passengers and sailors, causing complaints and dissatisfaction. Therefore, luxury cruises must control the vibration of the ship and the resulting noise (Braghin et al. 2011). At present, almost all classification societies have clear requirements for the vibration and noise of cruises. As the regulation goes, the noise level of all passenger compartments and public spaces shall comply with the requirements of IMO MSC 337 (91): *Ship Noise Level Rules* and ISO 6954 (2000): *Mechanical Vibration Guidelines*. For luxury cruises, the control of vibration and noise needs to be far stricter than normal ships in order to pursue higher comfort.

Structural Strength and Workload of Calculation

As an advanced passenger ship, a large luxury cruise requires high structural strength. The

requirements of the various specifications for cruise ship structures, given by some of the major western classification societies, namely, LR, RINA, BV, and DNV, are mainly concentrated on the calculation of structural strength, which involves the calculation of the longitudinal strength, the ultimate and remaining strength of the hull girder, the fatigue strength, and the strength of the entire ship. For the main supporting parts of the decks, the strength shall be directly calculated to check the tenacity. As for the ultimate and residual strength of the hull girders, besides the standard method, it can also be calculated by the nonlinear finite element method. In addition, the nonlinear finite element method can also be used to eliminate the noise of the ship (Fig. 2).

Structural Details

The luxury cruise should strive for excellence and each part requires exquisite work. Ship design workers in Japan and the West have attached great importance to the design and research of structural details. As a “mobile palace in the sea,” a large luxury cruise boasts a variety of sport, entertainment, dining, and leisure facilities. Every place and facility needs to be dedicated in design and manufacturing. Therefore, detailed design can also be a complex point for cruise design.

Design Specifications

The luxury cruise is not only a transportation vehicle but also a place for amusement. The

main functions of luxury cruise determine that the requirement is stricter than commercial ships in terms of safety, energy saving, and environmental protection.

Safe

Accidents of luxury cruises are generally caused by collision and cruise fire. Therefore, cruise ships must meet the requirements of *the International Convention for the Safety of Life at Sea* (SOLAS) and the requirements of *the Safe Return to Port* (SRtP). As SRtP notes, when a fire or flooding accident occurs, the ship should safely return to the port on its own power. During the process, passengers can safely stay within the “safety zone” and meet basic living needs. Even when the accident exceeds the safety zone, the ship should operate for at least 3 h to ensure orderly evacuation of passengers.

Eco-friendly

In order to create an eco-friendly marine environment, the International Maritime Organization (IMO) launched *Energy Efficiency Design Index (EEDI)* for controlling CO₂, sulfur oxide, and nitrogen oxide (SOX, NOX) emissions (Li et al. 2014). These rules will greatly affect the design of large luxury cruise.

Other Rules

International Labour Convention

The latest *Maritime Labour Convention, 2006* issued by the International Maritime Organization puts forward higher requirements for sailor’s living conditions. For example, the room area for

Luxury Cruises,

Fig. 2 Overall of vibration characteristics (<http://image.so.com/>)

four sailors should be larger than 14.5 m². However, many of the cruises built in recent years cannot meet this requirement.

Other Regulations

Among the cruise associations, *Cruise Lines International Association (CLIA)* is one of the most influential in the industry. The association has established the self-regulation rules widely followed by its members in the area of waste disposal, restricted access to the driving cab, extra life jackets, heavy weight fastening on ships, and passenger prototype exercises (Fig. 3).

The World’s Major Cruise Shipyards

Aker Shipyard, Finland

Aker Shipyard was established in 1738, which has a history of more than 270 years. Remarkably, decades ago, *Aker Shipyard* used to spend 2 years building the famous luxury cruise *Marine Independence*, which made a stir in the whole cruise community and replaced its sister ship *Marine Liberation*, becoming “the largest luxury cruise” in the world at that time (Wang et al. 2005).

Meyer Shipyard, Germany

Meyer Shipyard is one of Germany’s largest and most modern shipyards. It was founded in 1795 and mainly built of wooden boat at first and started the construction of iron ships in 1874. Its first indoor dock was completed in 1987, 470 m long, 101.5 m wide, and 60 m deep. In 2000, the

second giant indoor dock was built, with a specification of 504 m in length, 125 m in width, and 75 m in depth. The shipyard can build three luxury cruises per year.

Fincantieri Shipyard, Italy

Fincantieri shipbuilding corporation in Italy has a long history of designing and building warships for nearly 200 years. The main products are passenger liners, ferries, and submarines, representing Italy’s advanced industrial technology and export around the world. In particular, its passenger ships and luxury cruises reign at the world’s No.1, accounting for 40% of the international market.

Key Applications

The World’s Leading Luxury Cruise Company (Group)

Carnival Corporation & plc

Carnival Corporation & plc (Zhou et al. 2010) is the world’s largest cruise company and has a total of 11 cruise brands, including *Carnival, Aida, Costa, Princess, Holland, Crown, Ibolo, P&O, P&O Australian, Saab, and Ocean Village Classes*. The fleet operates in Europe, the Caribbean, the Mediterranean, Mexico, and the Bahamas throughout the year. Seasonal routes include Alaska, Hawaii, the Panama Canal, the Canadian shipping lines, etc. Its fleet advantage lies in its various leisure facilities and innovative and spacious compartments.

Luxury Cruises,

Fig. 3 Design specifications (<http://www.baidu.com/>)

Passenger ships, Passenger Accommodation Frequency weighted r.m.s values in mm/s from 1 Hz to 80 Hz.			
Location	Comfort rating number (crn)		
	1	2	3
Passenger, top grade cabins	1.5	1.5	2.0
Passenger cabins, standard	1.5	2.0	3.0
Public spaces	1.5	2.0	3.0
Open deck recreation	2.0	2.7	3.5
For passenger ships with comfort rating, no single frequency component within the frequency range 6.3 Hz to 12.5 Hz shall exceed 1 mm/s r.m.s (weight).			

Royal Caribbean Cruises Ltd

Royal Caribbean Cruises Ltd. is the second largest cruise company in the world and owns six major brands (*Royal Caribbean International (RCI)*, *Fine Diamond Cruises*, *Freedom Cruises*, *Pullmantur Cruises*, *CDF Cruises*, and *TUI Cruises*), 41 luxury cruises, and 460 diverse sailing lines. It can visit nearly 300 tourist destinations, covering more than 70 countries and regions including the Caribbean, Alaska, Canada, Europe, the Middle East, Asia, Australia, and New Zealand.

Genting Group

Genting Group is a leading cruise corporation in Malaysia, which is composed of five major subsidiary companies: *Genting Malaysia Berhad*, *Genting Plantations Berhad*, *Genting Singapore PLC*, *Genting Hong Kong Limited*, and *Kien Huat Realty*. Established in September 1993, *Genting Hong Kong* runs the cruise travel business in Asia under the brand of *Star Cruises*. It is considered to be a pioneer in the Asian cruise industry and is committed to develop the Asia Pacific region as an important international cruise destination.

MSC Cruises

MSC Cruises is the leader of the cruise market around the Mediterranean Sea with ships throughout the region all year round. At the same time *MSC Cruises* offers seasonal cruise journey around the world including destinations such as the Nordic Atlantic Caribbean North America South America South Africa and other places. Possessing one of the world's most modern fleets which consists of 11 cruise ships the corporation has achieved the number of 1.3 million tourists annually.

Norwegian Cruise Line

Founded in 1966, *Norwegian Cruise Line* is headquartered in Miami-Dade County, Florida, and has become one of the most well-known brands in the North American cruise industry. Together with the newly joined fleets *Ocean Class* and *Regent Seven Seas Class*, the corporation has a total of 23 cruise ships operating throughout North America, Hawaii, the

Caribbean, Alaska, Europe, the Mediterranean, and Bermuda. The company's major shareholders are *Genting Hong Kong*, *Apollo Global Management*, and *TPG Capital*.

Famous Luxury Cruises in the World

Queen Mary 2

Queen Mary 2 (shown in Fig. 4) is an ultra-luxury ocean liner affiliated to *British Canada Cruise Line Company*. The liner costs more than 800 million US dollars and has a displacement of about 150,000 t. *QM2* can be regarded as a star in the world's cruise and is currently the largest ocean liner, with more than 1250 sailors at service. What is truly impressive is the ship size. She is 345 m long and 72 m tall, which is taller than *the Statue of Liberty* and larger than the largest aircraft carrier in the United States.

Queen Mary 2 is honored for many advanced technologies. A powerful marine mechanical propulsion system enables the sculpting of the giant hull, and advanced navigation and communication equipment can make sailing safer.

MS Voyager of the Seas

MS Voyager of the Seas (shown in Fig. 5) is the lead ship of the *voyager-class cruises* operated by *Royal Caribbean International (RCI)*, with a displacement of 137,000 t, able to carry 3840 passengers. She was the largest five-star luxury cruise in Asia, 311 m in length and 39 m above the waterline. What is worth mentioning, the ship possesses a *royal ballroom*, which is larger than the size of two football field, and a huge theater, with a capacity of 1350 people.

The most famous facility on *MS Voyager of the Seas* is the 120-m-wide deck. It is connected to two 11-story halls at each end side of the deck. Under the *Royal Avenue*, there are special facilities such as skating rinks, basketball courts, mini golf courses, and sea climbing walls.

MS Explorer of the Seas

MS Explorer of the Seas (shown in Fig. 6) is a *voyager-class* cruise ship owned and operated by *Royal Caribbean International*. With a displacement of 138,000 t and 1138 sailors at

Luxury Cruises, Fig. 4 Queen Mary 2 (https://en.wikipedia.org/wiki/Ocean_liner)

Luxury Cruises, Fig. 5 MS Voyager of the Seas (https://en.wikipedia.org/wiki/Ocean_liner)

service, she can accommodate over 3100 guests. The ship is fitted with six powerful *Wartsila* engines and three podded propulsors. The hull is 311 m in length, 38 m in width, and 47 m above the waterline, providing enough activity space for passengers. Passengers can enjoy

skating, board walking, and cliff climbing on the ship.

Sea Adventurer

Sea Adventurer (shown in Fig. 7) is a luxury cruise managed by the Royal Caribbean “Voyager Class,”

Luxury Cruises, Fig. 6 MS Explorer of the Seas (https://en.wikipedia.org/wiki/Ocean_liner)

Luxury Cruises, Fig. 7 Sea Adventurer (https://en.wikipedia.org/wiki/Ocean_liner)

with a displacement of 138,000 t and 1180 sailors at service. She has a length of 311 m, a width of 38 m, and a height of 47.5 m above the waterline, which owns 667 standard compartments.

Adventure of the Seas is best known for her spectacular three-story themed restaurant, under which there is a huge stadium that can

accommodate 1350 spectators. Besides a skating rink, climbing walls, and golf courses, the stadium also features a large gymnasium including basketball, bowling, and volleyball venues. In addition, *Adventure of the Seas* also boasts a wedding chapel, a hallmark of luxury cruise ships.

Navigator of the Seas

Navigator of the Seas (shown in Fig. 8) is one of the cruise liners of *Royal Caribbean International*. She measures about 138,000 GT and carries 3807 passengers plus 1180 sailors. Her length amounts to 311 m with a width of 38 m, and the height above the waterline is about 49 m.

Navigator of the Seas has a learning room equipped with 19 personal computers, the famous “Navigator’s Library” with a collection of thousands of books, a world-renowned caravan piano bar coupled with a nightclub, two swimming pools, as well as a cosmopolitan theater that can accommodate 1359 seats. Other service facilities include the *Cloud Nine* cocktail lounge, a jazz club, and a golf bar. The most considerate design is the large game room outside the library. Here, the popular games and game facilities make young passengers immersed in joy.

Chinese Market Distribution and Future Development Trend

While the ship market continues to be in the doldrums, the large cruise market is still active (Duman and Mattila 2005). Cruise tourism is currently on a large scale in Europe and America. There are 300–400 cruises a day with a large

number of tourists sailing in Alaska, Canada, the Caribbean, Mexico, Bahamas, Hawaii, Bermuda, South America, Panama Canal, Northern Europe and Russia, the Mediterranean, Greece, United Kingdom, and more than 100 countries and regions in Asia and Australia. The voyage spreads over 7 continents and travels more than 260 ports around the world.

With the rapid growth of the cruise economy, the market potential of luxury cruise ships in emerging countries such as China has attracted the attention of global cruise giants. According to the analysis of *2016 China Cruise Industry Development Status and Prospects*, the demand of the cruise market in China is growing rapidly, for its rapid economic growth and large population (Sun et al. 2014). The market scale continues to expand, and the number of cruise ship visitors has experienced an explosive annual growth of over 40% in 2016 (Wang et al. 2018). Considering that the penetration rate of China’s luxury cruise tourism is still less than 0.2%, and the impact of future consumption upgrades and policy promotions, the huge development potential of China’s cruise industry can be optimistic in the future. It is expected that the Chinese cruise market will maintain a growth rate of over 30% in the next 5 years and will have more than nine million cruise visitors by 2020. It can be said that a cruise feast that

Luxury Cruises, Fig. 8 Navigator of the Seas (https://en.wikipedia.org/wiki/Ocean_liner)

focuses on Chinese market will kick off in the near future.

Definition

Maneuverability of polar vessel refers to the performance that the polar vessel can keep or change its motion state according to the intention of the pilot. It mainly involves the ability of polar ships to maintain or change speed, course, and position.

Introduction

The key principle for ships' successful ice navigation is to keep freedom of maneuver. Once a

Baoshan Wu: deceased.

ship is trapped, the ship goes wherever the ice goes. Ship maneuvering in ice-covered waters is far more complex than that in open water, given the reason that the ice-hull interaction is stochastic in nature, resulting in irregular icebreaking pattern with high uncertainty. To better understand polar ships' maneuverability, the maneuvering tests, maneuvering equations, maneuvering performance, and DP in ice are presented and further discussed.

Nomenclature

L	Ship's waterline length (L_{WL}) [m]	N_v	Derivative of yaw moment due to sway velocity [kg-m/s]
B	Ship's beam [m]	$Y_{\ddot{v}}$	Derivative of sway force due to sway acceleration [kg]
m	Mass [kg]	$N_{\ddot{v}}$	Derivative of yaw moment due to sway acceleration [kg-m]
C_b	Block coefficient	Y_{δ}	Derivative of sway force due to rudder angle [kg-m/s ²]
I_z	Yaw moment of inertia [kg-m ²]	N_{δ}	Derivative of yaw moment due to rudder angle [kg-m ² /s ²]
R_b	Icebreaking resistance [N]	Y_r	Derivative of sway force due to yaw rate [kg-m/s]
σ_f	Ice flexure strength [Pa]	N_r	Derivative of yaw moment due to yaw rate [kg-m ² /s]
H_i	Ice thickness [m]	$Y_{\dot{r}}$	Derivative of sway force due to yaw acceleration [kg-m]
l_{cr}	Crack length [m]	$N_{\dot{r}}$	Derivative of yaw moment due to yaw acceleration [kg-m ²]
D	Turning diameter [m]		
R	turning radius [m]		
R/L	Non-dimensional turning radius		
V	Forward speed [m/s]		
v	Lateral speed [m/s]		
$\dot{v}$	Lateral acceleration [m/s ²]		
R	Turning radius [m]		
r	Yaw rate [rad/s]		
$\dot{r}$	Yaw acceleration [rad/s ²]		
t	Time [s]		
x_G	Position of center of gravity [m]		
Y_0	Sway amplitude [m]		
K	Roll moment [N-m]		
N	Yaw moment [N-m]		
X	Surge Force [N]		
Y	Sway Force [N]		
T	Draft [m]		
x	Forward position from global origin [m]		
y	Lateral position from global origin [m]		
ϕ	Yaw angle [degrees]		
β	Drift angle [degrees]		
δ	Rudder angle [degrees]		
λ	Scale factor		
Y_v	Derivative of sway force due to sway velocity [kg/s]		

Maneuvering in Ice

The extreme environment in Polar Regions poses great challenges to ships' navigation, and ice is the primary factor that affects ship's maneuvering performance, especially to icebreakers. The typical circumstances ships would encounter in ice-covered waters are listed as follows. When the average ice thickness exceeds 50 cm, icebreakers cannot go forward with full speed due to high resistance from ice, and the channel behind icebreakers freezes quickly afterwards, in which case the ship is likely to be trapped. Besides, the shoulder of ship is easily wrecked either in turning or advancing owing to the inhomogeneity of ice. And if a ship encounters a crack, the bow is forced to slide along the edge of crack. This may lead to rudder out of control. When ice-ship interaction is acute, the shipborne equipment would likely to be damaged, and the motion of rudder is encumbered by ice, leading to difficulty of bow turning. Poor maneuverability is one of the most important reasons. Therefore, successful ice navigation calls for good maneuvering performance.

A ship's capability to maneuver in ice-covered waters depends on its available steering forces and its transverse/rotational resistance. Sufficient steering force and propulsive power are key

factors to overcome the increased turning moment generated by the ice force along the broadside during inception of a turn and to reach a steady turning rate.

Steering forces are realized through lift generated by water flow over the rudder(s), differential propeller shaft thrust, directional thrust capability (such as podded-propellers and adjustable propeller nozzle direction), bow thrusters, and lift generated from ship heel angle. A ship's transverse and rotational resistances are directly influenced by its L/B ratio, block coefficient, shape of the icebreaking waterline, and slope of the hull (or "icebreaking angle") along the icebreaking waterline, shape of its underwater hull, and its pivot point.

According to size, age, thickness, and concentration, ice can be classified into four primary types: broken ice, sheet ice, ridged ice, and icebergs (Aboulazm and Muggeridge 1989). Sheet ice, also called level uniform homogenous ice, is the most common and severe ice condition that ships (icebreakers and ice going ships) navigating in polar regions would encounter. Majority of full-scale maneuvering tests were carried out in sheet ice. Events associated with a ship maneuvering in level uniform homogenous ice can be categorized by ice thickness. For very thin ice, a ship's turning radius will normally be very near that of its open water turning radius. This is largely attributed to the icebreaking action of the bow wave. As ice thickness increases, the effect of the bow wave diminishes and the ice sheet begins to interact with the ship's hull. Ice breaking occurs mostly at the bow. The broken channel is wider than the ship's beam so that the stern can move out and point the bow into the turn. The sides and aft of ship also break ice. As ice thickness increases, the ship's ability to clear away broken ice from between its sides and the ice channel edges diminishes. A limiting ice thickness is approached where turning resistance is too high and the ship is no longer able to making turns at all. Quantitative values for ice thicknesses were not provided in the description because thickness alone does not dominate the ship-ice interactions. Ice strength, both in flexural and crushing, and hull-ice friction are also major influential factors. Besides, the authors also take into account the changes of broken channel edges to research the

phenomenon of icebreaking in aft shoulder of ships in level ice (a simplified model of sheet ice in model test and numerical simulation).

For other conditions, ice distribution (pack or rubble ice, ridges, etc.), ice pressure (e.g., due to wind), snow cover, surface current, and water depth also directly impact a ship's maneuvering performance. Pack or rubble ice is usually a common condition for ice going ships and ice-strengthened ships (Riska 2010). Turning and zig-zag are two main maneuvers in pack ice according to the real navigation. And this was simulated by Zhan et al. adopting DEM method (Zhan and Molyneux 2012).

Equation of Motion in Ice

Coordinate Systems

In ship maneuvering simulations, the ship can be regarded as a rigid body. The co-ordinate systems (Fig. 1) and equations of motion of ship maneuvering in ice are the same as that in open water. And the surge force, sway force, and yaw moment are the three major global forces to determine the ship's maneuvering motions (Zhou et al. 2016).

$$\begin{cases} m(\dot{u} - rv) = X \\ m(\dot{v} + ru) = Y \\ I_z \dot{r} = N \end{cases} \quad (1)$$

Maneuverability of Polar Vessel, Fig. 1 Coordinate systems

External Forces

The external forces include forces from the hull, the thruster, the rudder, and other appendages. During ship's ice navigation, forces on the hull mainly consist of ice forces, hydrodynamic forces, current forces, and wind forces. See Fig. 2.

The forces from appendages and other environmental factors like wind are usually ignored. Until now, most researchers divide external forces into several parts, which is (Lubbad and Løset 2011):

$$\begin{cases} X = X_H + X_P + X_R + X_{Ice} \\ Y = Y_H + Y_P + Y_R + Y_{Ice} \\ N = N_H + N_P + N_R + N_{Ice} \end{cases} \quad (2)$$

H, P, R, and ice represent forces and moment generated from hydrodynamic force, propeller force, rudder force, and ice load, respectively.

Ice Force

The basic premise to get ice force is to understand the mechanics of ice-ship interaction. Two categories, analytical approach and numerical approach, are used to classify the existing models of ice-ship interaction process. In terms of analytical approach, the methodology in which the total

ice force is divided into several independent force components that represent the corresponding physical processes during the continuous ship maneuvering in level ice has been widely used. The global ice force is equal to the linear sum of the three force components, that is, the breaking, buoyancy, and clearing force components. It can be written as:

$$\begin{cases} X_{ice} = X_{br} + X_{cl} + X_{bouy} \\ Y_{ice} = Y_{br} + Y_{cl} + Y_{bouy} \\ N_{ice} = N_{br} + N_{cl} + N_{bouy} \end{cases} \quad (3)$$

The ice breaking force component represents the contributions from the ice breaking process which is stochastic in nature resulting in irregular icebreaking pattern with high degree of uncertainty in predictability during ship maneuvers. To get ice force by numerical approach is mainly depends on its numerical model.

Overview of Ship Maneuvering Prediction in Ice

To predict ship maneuvering performance in ice, a model applying the analytical approach with

Maneuverability of Polar Vessel, Fig. 2 Ice-ship interaction in maneuvering (Liu et al. 2007)

numerical implementation for simulating various ship maneuvers in level ice is established. The model is used to simulate real-time maneuvering and support maneuvering simulator for its efficiency. Also, numerical methods have witnessed great advancement with the development of the computer technology. They can be used to solve analytical equations or to simulate the continuous ship-ice interaction process in various ice conditions (Liu et al. 2007).

Analytical Approach

The analytical approach is subdivided into empirical, semi-empirical models.

With a large number of ship model tests and full scale ship trials having been carried out, experimental data (e.g., coefficients) can be obtained through sorting and fitting test results. Majid and Menon et al. (1983) built a time domain model for ship maneuvers in ice based on conventional maneuvering equations. The Taylor's series expressions with coefficients obtained from model tests were adopted to estimate the ice forces on the hull due to the ship motion in the level ice. Williams et al. (1996) proposed an ice-hull force model for ship maneuvers in level ice from a series of PMM model tests. Robert et al. (2002) conducted a series of resistance and maneuvering tests using the R-class icebreaker model (scale ratio 1:40) and MV Arctic Bulk Carrier model (scale ratio 1:80), in which the damping coefficient and the acceleration control coefficient of the roll were calculated. Lau et al. (2004) discussed the effect of breaking channel width on ship maneuverability from PMM tests. And the effect of external moment on ship-ice interaction was also studied. Li et al. (2013) conducted a series of model tests on icebreaker in ice basin. The change of model speed and heading angle in different ice thickness were analyzed. Phenomena such as bending broken on ice and ice crushing on hull surface were observed.

The analytical models applying semi-empirical approaches take into account more details of the pertinent ship-ice interaction processes. Tue-Fee et al. (1987) proposed a semi-empirical model for predicting ship's steady turning maneuvers in level, unbroken, homogeneous ice fields. The

formulas for calculating sway force and yaw moments caused by pure ice forces are theoretically derived from basic assumptions. Aboulazm (1993) theoretically analyzed the turning performance of the ship in the block ice condition, and the external force of the ship in steady turning was calculated.

Numerical Approach

Discrete element method (DEM), which divides the continuous ice materials into many small elements, is widely applied in ice mechanics issues. Based on DEM, Lau (2006) simulated advancing and turning motion of TERRY FOX numerically using commercial discrete element code software. The ship was regarded as rigid body, and both level ice and ship model were established in discrete elements. The numerical results were compared with PMM model test results, which agreed very well. The shortcoming is that ice model was greatly simplified, and the failure of old discrete elements and the generation of new discrete units were not considered. Sawamura (2010) also calculated ship maneuvering in level ice using DEM model. The level ice in waterline surface was divided into a number of small circles, and the disappearance of circles indicated the breaking of the ice. This method is a good way to observe the maneuvering trajectory, yet it only paid attention on the ice force near the waterline, ignoring the friction of the broken ice along the hull. Many other researchers have also contributed greatly to this problem, such as Zhan et al. (2010), Zhan and Molyneux 2012, Derradji (2003), Valanto (2001).

Another common numerical model was polygon model. This method is a 2D numerical solution, in which the broken channel edges and the ice breaking in ships' aft shoulder during turning are observed in detail. This method can be found in Martio (2007), Su et al. (2010), and Zhou (2016).

Maneuvering Tests in Ice

Maneuvering test is a collective name for all those tests in which the rudder is turned or the turning forces and moments are obtained by other means,

for example, azimuthing thrusters, tunnel thrusters in bow, different rpms at twin propellers. The primary purpose of maneuvering tests is to investigate the effectiveness of the hull in making turns. The other considerable purpose is to investigate the effectiveness of the turning devices like rudders, thrusters, or azimuthing propulsors. Maneuvering tests are also applied to investigate the flow of ice floes around the hull in various maneuvers. The design of aft shoulders down to baseline is especially important for turning capability. Quinton et al. (2005) had collected test data of all publicly available full-scale and model-scale ship-ice maneuvering data before 2005.

Full-Scale Ice Maneuvering

In terms of full-scale ice maneuvering, common maneuvers conducted by icebreaking ships are: (1) ahead progress, (2) channel breakout, (3) turning circle, (4) captain's turn, (5) modified captain's turn, (6) Kempf maneuver (or zig-zag), (7) breaking out a beset ship, (8) close coupled escort, and (9) ridge ramming. The turning circle and the Kempf maneuver are the most common of all in a "maneuvering in ice" performance evaluation.

The purpose of the turning circle test is to find out how much area is needed to turn the ship. In practice, the circle may not be a perfect circle, but

a spiral. The progress of this test is just like that in open water (Fig. 3), which involves four phases. However, the detail of external force acting on the hull is different because of the ice. In open water, steady turning radius R is the simplest measure of a ship's maneuverability, while the situation is different in ice condition. Because variations in ice thickness and strength also affect the ship's maneuverability, R/L is not as reliable a representative of "maneuvering performance in ice" as it is for open water. Yet, most researchers consider this parameter as a standard. Generally, the smaller the R/L values for a ship, the greater its ability to maneuver while keeping continuous motion. Some modern icebreaker designs are able to turn the ship in level ice so effectively, that the diameter of the broken area in ice is almost the same as the waterline length of the ship.

The turning ability is not the only measure for the maneuvering performance of an ice-going ship. It is important to perform different maneuvers (e.g., zigzag and star maneuvers) in shortest time possible. A good maneuvering performance can be achieved by a proper hull form design, having a large turning rate of the rudder(s) or azimuthing thruster(s) and providing a large transverse force.

Breaking out of channel test is mainly conducted by merchant ships. Those ships

Maneuverability of Polar Vessel, Fig. 3 Turning circle schematic (ITTC Dictionary of Hydromechanics)

navigate mostly in channels made by icebreakers. Therefore, the turning circle is not a relevant description of the agility of the ship but the ability of the ship to turn out from a channel. The test can be performed from zero speed or some other specified speed. The channel width and local pattern of ice floes and shapes of the channel edges (before the test) have big influence on the results. If this test is performed from zero speed in the channel made by the test in presawn ice, the result may differ from that in naturally broken channel.

A lot of full-scale maneuvers in ice were conducted, for example, Max Waldec, Coast Guard 140 Foot Icebreaker, Canmar Kigoriak, Robert LeMeur, USCGC Polar Star, USCGC Healy, AHTS/IB Tor Viking II. The database of tests can be found in Quinton et al. (2005).

Model-Scale Ice Maneuvering

Ice maneuver tests in model scale can be grouped into two categories, that is, free running model test and captive model test.

The free maneuver tests involve the use of a remotely operated model that is unrestricted and capable of self-propulsion and steering. An operator directs the model via remote control and a model tracking system recording its motions. Two maneuvers in particular are used to test the maneuvering performance of free running models in ice: turning circles and Kempf maneuvers. The general process is to place the model on one side of the ice sheet, and then setting the power. The rudder angle will be given until the ship model runs straightly and steadily, and the turning diameter can be measured by running out of the 1/4 turn path. The self-propelled model test can directly observe the maneuverability of the ship model in different ice condition, but the scale of ship model is usually limited by the scale of the ice tank. And it costs a lot. A free maneuver test conducted by NMRI (National Maritime Research Institute) in Japan (Izumiyama et al. 2005) found the difference of ice load distributions in the turning-going. In the turning mode, significant ice loading occurs in the aft-body in the outside of the turn, while the inside hull receives very little load.

Captive maneuver tests involve the use of some form of Planar Motion Mechanism (PMM)

or a combination of devices that cause the same motion control (e.g., a rotating arm in combination with other devices). The purpose of PMM test is to obtain a series of hydrodynamic and derivatives which govern the maneuvering performance of a ship. Six standard PMM tests, including static rudder, yaw sweep, pure sway, pure yaw, and pure yaw with drift, are carried out to get forces and moment of the model. Ship maneuvering characteristics can be predicted afterwards. The Institute for Ocean Technology (IOT) in Canada has performed a series of model tests using its PMM. A PMM test (Lau 2007) was conducted by the institute in manifold conditions, and the process of PMM test was described in detail.

DP in Ice

With an increasing interest of operations in Arctic and subarctic areas, the station-keeping capabilities in ice have attracted wide attention. Vessels operating in various ice conditions require suitable dynamic positioning (DP) systems to help course-keeping or position-keeping. DP is widely used in ice-free waters and open seas where the impacts from wind, waves, and currents are involved in the force balance algorithms.

DP in ice conditions infers additional parameters such as the local and global ice loads on hull and the performance variations of propulsion systems. To understand and predict the ice forces acting on a DP ship, a wide range of numerical simulation studies and development projects have been initiated throughout the years. The numerical simulations focus on a wide range of applications from hull and propulsion designs, DP capability limits, ice management, and oil spill response capabilities evaluation to operational training for navigational officers.

²Ocean College, Zhejiang University, Zhoushan, China

Synonyms

Ecological sensitive areas; Ecological vulnerable areas

Definition

The marine ecological red line is a marine spatial planning tool, referring to the institutional arrangement of important marine ecological functional areas, ecological sensitive areas, and ecological vulnerable areas as key control areas which implement strict classified management and control measures in order to maintain marine ecological health and security.

Scientific Fundamentals

The Origin and Development of the Red Line System

The red line was originally defined as a red sign warning the maximum safe flight speed or a red line marking other hazardous bases. “Red line”

as a spatial planning tool was first used in China by a Chinese scholar Dr. Gao Jixi when he was doing ecological planning in Anji County, Zhejiang Province, in 2000 (Gao 2014). In 2006, the State Council formulated the cultivated land red line of 1.8 billion mu (1 mu = 666.6666667 square meters), which was the first management policy officially named as “red line” in China. Subsequently, the concept of red line was gradually introduced into the field of resources and environment, and related concepts such as water resources red line and forestry red line were derived. The connotation of red line also expanded from spatial constraints to quantitative constraints (Rao et al. 2012). By the end of 2020, China completed the national ecological protection red line delineation; by 2030, China’s ecological protection red line layout will be further optimized (Fig. 1). So far, the ecological red line system has risen to the height of national strategy and has become a new system to guide China’s social and economic development. It is also an innovative measure in regional ecological protection and management in China.

Principles of Marine Ecological Red Line Zoning

There are five key principles in marine ecological red line zoning.

1. Regional conjugation. Any marine ecological red line area must be a relatively complete, scarce (unique) natural geographical unit, and its scope should include the key areas to maintain the integrity and connectivity of the

Marine Ecological Red Line, Fig. 1 Timeline of red line policy development in China

- ecosystem, so as to ensure the flow and transmission of ecosystem material, energy, and information.
2. Ecological orientation. The scientific knowledge of ecosystem and its dynamics should be used to guide the division of marine ecological red line, with emphasis on the specific ecosystem and the influence range of various activities.
 3. Integration of land and sea development. It is necessary to fully consider the internal relationships between ocean and land resources, natural environment and ecology, correctly handling the links between ocean and land ecological protection, as well as formulating strategic thinking of the integrated development of sea and land.
 4. Coordination principle. Marine ecological red line zoning should be connected with land ecological red line zoning as far as possible, coordinating with the boundaries of various marine ecological protection areas, adapting to the needs of economic and social development as well as the local regulation ability, and reserving appropriate future development space and environmental capacity space.
 5. Dynamic principle. Marine ecological red line zoning should be forward-looking, and the area should only be increased but not be decreased. Whenever the boundary and threshold of the ecological red line zone has changed due to the disturbances from the external environment, it should be adjusted in time to ensure the continuity of its basic ecological process and function.

Theoretical Basis of Marine Ecological Red Line

Ecological succession (Wikipedia 2021a) is the process of change in the species structure of an ecological community over time. The time scale can be decades (e.g., after a wildfire), or even millions of years after a mass extinction (Sahney and Benton Michael 2008). It is a phenomenon or process by which an ecological community undergoes more or less orderly and predictable changes following a disturbance or the initial colonization of a new habitat. Succession may be

initiated either by formation of new, unoccupied habitat, such as from a lava flow or a severe landslide, or by some form of disturbance of a community, such as from a fire, severe windthrow, or logging. Succession that begins in new habitats, uninfluenced by preexisting communities, is called primary succession, whereas succession that follows disruption of a preexisting community is called secondary succession. Succession is among the first theories advanced in ecology, and the study of succession remains at the core of ecological science.

A coupled human-environment system (Wikipedia 2021b) (known also as a coupled human and natural system, or CHANS) is an integrated scientific framework for studying the interface and reciprocal interactions that link human (e.g., economic, social) to natural (e.g., hydrologic, atmospheric, biological) sub-systems of the planet (NSF, Marina et al. 2011). The phrase “coupled human-environment systems” appears in the earlier literature (dating back to 1999) noting that social and natural systems are inseparable (Sheppard and McMaster 2004, NRC 1999). Research into CHANS builds on the disciplines of human ecology, ecological anthropology, environmental geography, economics, and other eco-bio-geo-physical fields. Moving beyond some of the traditional research methods in social and natural sciences, CHANS tackles broader investigations into the complex nature of reciprocating interactions and feedbacks between humans on the environment and the effect of the environment on humans.

The theory of human-sea relations. In a narrow sense, it means that human society, in order to survive and develop, constantly expands and deepens the transformation and utilization of the marine environment (Kappel et al. 2012), enhances the ability to adapt to the marine environment, and changes the appearance of the marine environment; in turn, the marine environment also affects human activities, resulting in sea area differences. There is a unity-contradiction between them.

Sustainable development (Wikipedia 2021c). Economic development ensures that environmental depletion and degradation do not occur. In the

late 1980s, the term came to have a wider application as concern with environmental issues grew. Criteria of sustainable development came to be applied to all forms of economic development. Hitherto those economic developments had ignored environmental effects that could undermine those developments. So sustainable development would be seen as economic and social development that could avoid pollution, conserve nonrenewable energy forms, and in general would not cause future problems for which there were no easily available solutions.

The carrying capacity (Wikipedia 2021d) of a biological species in an environment is the maximum population size of the species that the environment can sustain indefinitely, given the food, habitat, water, and other necessities available in the environment. In population biology, carrying capacity is defined as the environmental maximal load (Hui 2006), which is different from the concept of population equilibrium. The carrying capacity is the number of individuals an environment can support without significant negative impacts to the given organism and its environment. Below carrying capacity, populations typically increase, while above, they typically decrease. A factor that keeps population size at equilibrium is known as a regulating factor. Population size decreases above carrying capacity due to a range of factors depending on the species concerned but can include insufficient space, food supply, or sunlight. The carrying capacity of an environment may vary for different species may change over time due to a variety of factors, including food availability, water supply, environmental conditions, and living space.

The balance of nature (Wikipedia 2021e) is a theory that proposes that ecological systems are usually in a stable equilibrium (homeostasis), meaning that a small change in some particular parameter (e.g., the size of a particular population) will be corrected by some negative feedback that will bring the parameter back to its original “point of balance” with the rest of the system. It may apply where populations depend on each other, for example, in predator/prey systems or relationships between herbivores and

their food source. It is also sometimes applied to the relationship between the Earth’s ecosystem, the composition of the atmosphere, and the world’s weather.

Theoretical paradigm of delimitation of marine ecological red line. The delimitation of marine ecological red line should be based on the ecological integrity of marine resources and environment, and natural interference and human interference should be regarded as external interference. The delimitation of marine ecological red line should be based on finding the threshold between disturbance pressure and ecological integrity in the process of system development and formulate the threshold value of spatial resources, environmental elements, and ecological protection.

Key Applications

National Marine Red Line Policy in China

Review and Comparison of National Policies

In recent years, the state has paid more and more attention to the delimitation, management, and supervision of marine ecological red line and promulgated many important policies. In 2018, the State Oceanic Administration (SOA) promulgated the “measures for supervision and administration of the red line of marine ecological protection (Draft for comments),” pointing out that the implementation of the national marine ecological protection red line should be uniformly guided, coordinated, and supervised by the State Oceanic Administration. The provincial marine administrative departments shall, in accordance with the law, organize and implement the management and control of marine ecological protection red line areas, marine ecological environment monitoring, and ecological protection and remediation. This method mainly makes detailed requirements for sea-related review, assessment and supervision, regular evaluation, monitoring, and so on. In 2019, the Ministry of Ecological Environment issued the “measures for the management of ecological protection red line (Trial)” (Draft for comments). It pointed out that local governments at all

levels are responsible for delimiting and strictly abiding by the ecological protection red line, and the department in charge of ecological environment under the State Council, together with relevant departments, shall formulate policies and standards for delimiting and strictly observing the ecological protection red line. The departments in charge of ecological environment at all levels shall exercise unified supervision over the red line of ecological protection in their respective administrative areas and carry out unified monitoring and evaluation, supervision and law enforcement, and supervision and accountability. Relevant departments in charge of development and reform, finance, natural resources, water conservancy, agriculture and rural areas, forestry, and grassland at all levels shall, in accordance with their respective responsibilities, do a good job in protecting and managing the red line of ecological protection. The measures mainly regulate and restrict the delimitation and adjustment of red line, human activity control, protection and restoration, and ecological compensation. In 2020, the Ministry of Natural Resources issued the “ecological protection red line management measures (Trial)” (Draft for comments). The measures pointed out that the department in charge of natural resources under the State Council, together with relevant departments, should formulate and improve policies for delimiting and managing ecological protection red lines, establish and improve relevant technical standards and regulatory systems, and guide the delimitation and management of ecological protection red lines in all provinces (regions and cities). According to the land and space planning, the local natural resources departments at all levels shall establish a red line coordination mechanism for ecological protection and uniformly carry out the work of use control, monitoring and evaluation, supervision and law enforcement, and assessment and evaluation. The measures have detailed regulations on the red line delineation and adjustment, limited human activity control, supervision, and implementation, covering the main aspects of the two measures issued in 18 and 19 years, with relatively complete and comprehensive contents.

Detailed Introduction of National Policies

Measures for Supervision and Administration of the Red Line of Marine Ecological Protection (Draft for comments) in 2018. The “red line of marine ecological protection” determined the boundary line of geographical area and the control line of relevant management indicators of important marine ecological functional areas, marine ecological sensitive areas, and marine ecological vulnerable areas. The red line of marine ecological protection is the bottom line of maintaining marine ecological function and marine environmental quality, which cannot be adjusted in principle. After the delimitation of the red line of marine ecological protection, the red line area, the retention rate of the natural coastline of the mainland, the retention rate of the natural shoreline of the island, the sandy coastline of the island, and the quality of the sea water can only be increased, but not reduced. In terms of monitoring and inspection, it is stipulated that the implementation of the red line of marine ecological protection should be included in the content of national marine supervision. The provincial marine administrative department shall establish a dynamic monitoring platform for the marine ecological protection red line in the administrative area to monitor the development and utilization activities and ecological environment status of the islands in the marine ecological protection red line area and the surrounding sea areas and report the annual monitoring results to the marine regional Branch Bureau before the end of December of each year. The State Oceanic Administration carries out assessment on the implementation of marine ecological protection red line of coastal provincial government. The assessment contents mainly include the implementation of marine ecological protection red line control indicators, implementation of control measures, and protection and restoration of marine ecological protection red line areas. In terms of public supervision, any unit or individual has the right to report to the marine administrative departments at all levels any behavior that violates the red line system of marine ecological protection, and the marine administrative department receiving the report shall deal with it according to law and regulations.

Measures for the management of ecological protection red line (Trial) in 2019 (Draft for comments). It is stated that areas with special important ecological functions within the scope of ecological space must be strictly protected. It is the bottom line and lifeline to ensure and maintain national ecological security. It usually includes important ecological function areas with important water conservation, biodiversity maintenance, soil and water conservation, wind prevention and sand fixation, coastal ecological stability, soil erosion, land desertification, rocky desertification, salinization, and other sensitive and fragile areas of ecological environment. In order to delimit and strictly observe the ecological protection red line, we need to establish the ecological protection red line system, ensure the national ecological security, and build a beautiful China, and these measures are formulated in accordance with the requirements of several opinions on delimiting and strictly observing the ecological protection red line and relevant laws and regulations. In principle, the ecological protection red line shall be managed according to the requirements of prohibited development areas. This method follows the principles of ecological priority, strict control, and equal emphasis on rewards and punishments. All kinds of development activities that do not conform to the main function orientation are strictly prohibited. According to the orientation of dominant ecological function, differential management should be implemented to ensure that the ecological function, area, and nature of ecological protection red line will not be reduced. In terms of human activity control, urbanization and industrialization activities are prohibited within the ecological protection red line, and all kinds of development activities that do not conform to the main function orientation are strictly prohibited. The measures list specific items of prohibited activities and permitted activities and formulate approval rules for human activities or construction projects within the ecological protection red line. The management of existing human activities and construction projects within the red line of ecological protection should follow the principles of respecting history, seeking truth from facts, handling according to

law, and gradually solving problems and strictly investigate and deal with illegal construction projects. In addition, the measures also require all localities to formulate ecological protection red line protection and restoration plans, give priority to the protection of good ecosystems and important species habitats, repair damaged ecosystems, build ecological corridors and important ecological nodes, and improve the integrity and connectivity of the ecosystem. In accordance with the principle of overall planning and comprehensive management of land and sea, it shall carry out ecological renovation and restoration of the ecological protection red line of marine land and space and focus on strengthening the comprehensive renovation of estuaries, coastal zones, islands, and polluted sea areas within the ecological protection red line.

Ecological protection red line management measures (Trial) in 2020 (Draft for comments). They are the areas with special important ecological functions in the land and marine ecological space which must be strictly protected under compulsion. These areas include water conservation, biodiversity maintenance, soil and water conservation, windbreak and sand fixation, coastal protection and other ecological functions of extremely important areas, soil erosion, land desertification, rocky desertification, coastal erosion and sand source loss and other ecologically vulnerable areas, as well as other areas with potential important ecological value which cannot be determined at present. In order to formulate and strictly observe the ecological protection red line, establish the ecological protection red line system, ensure the national ecological security, and build a beautiful China, these measures are formulated in accordance with the requirements of “several opinions on delimiting and strictly observing the ecological protection red line” and relevant regulations. According to the national and regional ecological security pattern and on the basis of scientific assessment, all provinces (districts and cities) shall identify areas with extremely important ecological functions and extremely fragile ecology, and other areas with potential important ecological value that cannot be determined by assessment at present, and shall be included in

the red line of ecological protection, so as to make sure that they should be fully delineated and protected. The demarcation of ecological protection red line should coordinate the contradictions and conflicts with permanent basic farmland, urban development boundary, and existing land space development and utilization activities, so as to ensure that the three control lines do not cross and overlap. In order to maintain the continuity and integrity of the ecosystem, scattered cultivated land, garden land, artificial commercial forest, artificial grassland, improved grassland, transportation, communication, energy pipeline, power transmission and other linear infrastructure, wind power, photovoltaic, marine energy and other facilities, and military, cultural relics, religious, funeral, and other special land in areas with extremely important ecological functions and extremely fragile ecology can be designated to enter the red line of ecological protection. Within the red line of ecological protection, in principle, human activities are prohibited in the core natural reserves, and development and productive construction activities are strictly prohibited in other areas. Once the red line of ecological protection is delimited, it shall not be adjusted without legal procedures. All localities are not allowed to adjust the ecological protection red line by modifying the land spatial planning at the city, county, and township level without

authorization. The regulations and requirements for transfer in and adjustments of nature reserves and transfer out (major national projects involving land/Sea Island) in the adjustment of red line are introduced in detail. At the end of the “measures,” social supervision, performance appraisal, and accountability are emphasized. The whole management method provides a good system guarantee for ecological protection red line. Due to the institutional adjustment and the state’s attention to the red line, it is believed that the state and local governments will issue further regulations on delimitation, management, and supervision in the next few years.

Red Line Delineation Methods: “Double Evaluation”

“Double evaluation,” the abbreviation of the evaluation of resource and environmental carrying capacity and territorial development suitability, is the important basis and prerequisite for the implementation of spatial planning (Fig. 2). The evaluation of resources and environment carrying capacity is a comprehensive evaluation of natural resources endowment and ecological environment background. The evaluation of territorial development suitability, on the premise of maintaining ecosystem health, comprehensively considers the suitability of human activities such as agricultural production, urban construction, and so on, by

Marine Ecological Red Line, Fig. 2 Technological system evolution in the field of “double evaluation” in China (Tian and Liu 2020)

comprehensively considering the resources and environment elements, location conditions, and specific land space. Based on the integrated evaluation results of “double evaluation,” ecological protection red line could be delineated.

According to the “requirements of several opinions on the establishment of land space planning system” and supervision of implementation issued by the CPC Central Committee and the State Council as well as the “notice on comprehensively developing land and space planning” issued by the Ministry of Natural Resources, the “double evaluation” has become the basis for optimizing the spatial pattern of land and the prerequisite for the compilation of land and space planning. As an important basis of land and space planning, “double evaluation” plays an important role in finding out the basic background of land space, ensuring the scientificity and rationality of land space planning, supporting ecological restoration and land space policy-making. “Double evaluation” is the reference basis for delimiting marine ecological protection red line and determining land and sea use planning indicators.

Due to the richness of the connotation of ecological red line, the demarcation methods of ecological red line are diverse, and there is no unified standard for dividing ecological red line. Based on the importance of ecological function and ecological vulnerability, the existing method for dividing ecological red line is to use geographic information system (GIS) for spatial analysis and processing.

Relationship and Difference Between Marine Ecological Red Line Zoning and Existing Marine Zoning

Marine ecological red line zoning is closely related to marine main function zoning, marine reserve, and marine functional zoning, but there are some differences (Table 1). As the basic and restrictive planning of marine space development in China, marine main function zoning has a wider scope of action and stronger effectiveness than other plans. Marine main function zoning plays an important role in guiding other marine-related planning and is an important carrier and way to

ensure the implementation of marine ecological red line zoning, and marine ecological red line zoning and marine function zoning are the important basis of marine main function zoning.

Marine protected areas (MPAs) refer to the areas designated in accordance with the law for special protection and management of coasts, estuaries, islands, wetlands, or sea areas, including the protected objects, for the purpose of marine natural environment and natural resources protection. The core factor of the value of marine reserves is the inherent scarcity and typicality of the protected objects, which is also applicable to the marine ecological red line areas.

Marine functional zoning (MFZ) is a type of marine spatial planning implemented widely in China and one of the three major systems defined in the Law of the PRC on the Administration of Sea Area Use. China adopts “top-down management” for MFZ, in which upper management levels impose clear constraints and restrictions on lower levels. The sea area is divided based on its geographical location, natural resources, natural environmental conditions, and social needs. It is used to guide and restrict the practical activities of marine development and utilization and ensure the economic, environmental, and social benefits of marine development. Marine functional zoning refers to all kinds of functions based on human needs. It emphasizes the economic attribute that the ocean can be used by human beings to produce use value, and it is a man-made overall arrangement of sea area use positioning. Therefore, marine functional zoning is essentially a management method to implement protection in development.

Case of Study

Currently, coastal regions in China are carrying out marine ecological red line zoning. Most of the regions have carried out extensive scientific research for zoning.

The people’s Government of Guangdong Province promulgated and implemented “the outline of the environmental protection plan for the Pearl

Marine Ecological Red Line, Table 1 Differences and relations of several current marine zoning in China

Zoning type	Marine principle function zoning	Marine functional zoning	Marine ecological red line zoning	Marine protected area
<i>Resource development and protection</i>	The optimized and key development zones focus on development, while the restricted and prohibited development zones focus on ecological protection	Develop and protect according to function plan	Strict protection	Restrict human activity
<i>Zoning basis</i>	Environmental carrying capacity, current development density, and development potential of marine resources	Sea area location, natural resources, environmental conditions, and requirements for development and utilization	Marine natural attributes, resources and environmental characteristics, regional ecological sensitivity and vulnerability, ecological importance	Intertidal zone and subtidal zone protected by law or other effective means, including the plants, animals, historical sites, and cultural characteristics inside the area
<i>Purpose</i>	Establish a rational development order, optimize the allocation and utilization of marine resources, protect the environment, and promote sustainable development	Guide the use of sea areas, protect and improve the marine ecological environment, and promote the sustainable utilization of resources	Maintain the integrity and connectivity of regional marine ecosystem	For a conservation purpose, typically to protect natural or cultural resources (MPA 2016)

River Delta” (2005), which put forward a complete ecological red line for the first time in the field of environmental planning. In 2014, Tianjin divided the red line area into six categories, mountains, rivers, lakes, wetlands, parks, and forest belts, and determined the proportion of different zones, and then strictly controlled the corresponding ecological regions. So far, the urban ecological red line system has basically formed. Based on the analysis of the system structure of ecological, water, atmosphere, and other environmental elements, the environmental protection intensity level of each region is determined based on the sensitivity and vulnerability of the areas affected by pollution formation and transmission process, and the important difference of the protection area, and the management is carried out with hierarchical management and control measures. In February 2014, the Ministry of Environmental Protection issued “the national ecological protection red line - Technical Guide for

delimiting ecological function baseline (Trial),” and in June 2016, the Oceanic Administration issued “the technical guide for delimiting marine ecological red line.” These guidelines have a good guiding role for the development and practice of ecological red line theory and delimitation technology in China.

Marine Operations

Lin Li

Department of Mechanical and Structural Engineering and Materials Science, University of Stavanger, Stavanger, Norway

Definitions

Marine operations are nonroutine operation of a limited defined duration related to handling of

object(s) and/or vessel(s) in the marine environment during temporary phases (DNVGL 2017). A marine operation is a process involving interactions between dynamic systems, operational procedures, environmental actions, and human intervention. A marine operation shall be designed to bring an object from one defined safe condition to another.

Examples of Marine Operations

Marine operations include a large variety of activities. The definitions of the following commonly used operations are provided (DNVGL 2016).

- **Towing:** The transfer at sea from one location to another location of a self-floating structure or a structure resting on a barge by pushing/pulling by tugs.
- **Launching:** The activities comprising cutting of sea fastening of a structure resting on a launch barge, the structure's slide-down on the launch rails on the barge and diving into the water until the structure is free floating.
- **Lifting:** The activities necessary to lift or assist a structure by a crane.
- **Load transfer operation:** The operation to transfer the load (i.e., an object) from/to vessel(s) without using cranes, that is, by using (de-)ballasting. Typical load transfer operations are load-out, lift-off, mating, and float-over.
- **Pipelay:** The operation of assembling and laying the pipeline on the seabed, from start-up point to lay-down point.

General Terms Related to Marine Operations

The relevant terms on marine operations are defined as follows (DNVGL 2016):

Operation Reference Period

Duration of marine operations shall be defined as an operation reference period, T_R .

$$T_R = T_{POP} + T_C \quad (1)$$

where T_{POP} is the planned operation period, and T_C is estimated maximum contingency time. T_{POP} shall be based on a detailed schedule for the

operation. In early planning phase, where a detailed schedule is not available, T_{POP} can be based on experience with similar operations. T_C should cover the general uncertainty in T_{POP} , the unproductive time during the operation, and possible contingency situations that will require additional time to complete the operation.

Weather Restricted and Weather Unrestricted Operations

An operation shall be defined as weather restricted or weather unrestricted based on its reference period.

Marine operations with a reference period (T_R) less than 96 h and a planned operation time (T_{POP}) less than 72 h may normally be defined as weather restricted. However, in areas and/or seasons where the duration of the reliable weather forecast is less than 96 h, the maximum allowable T_R is the duration of the reliable forecast. A weather restricted operation shall be planned to be executed within a reliable weather window. If the weather restricted design environmental condition is too low, severe waiting on weather delays can occur.

Marine operations that cannot be defined as weather restricted shall be defined as weather unrestricted operations. Environmental criteria for these operations should be based on long-term statistics. If found beneficial, operations of shorter duration may also be defined as weather unrestricted.

Operational Limiting Criteria

Operational limiting environmental criteria (OP_{Lim}) shall be established and clearly described in the marine operation manual. OP_{Lim} shall not be taken greater than the minimum of: (a) the environmental design criteria, (b) maximum wind and waves for safe working and object handling or transfer conditions for personnel, and (c) weather restrictions for equipment.

Forecasted and Monitored Operational Limits, Alpha Factor

Uncertainty in both the monitoring and the forecasting of the environmental conditions shall be considered. This should be done by defining a

forecasted (and, if applicable, monitored at the operation start) operational criteria, OP_{WF} :

$$OP_{WF} = \alpha \times OP_{Lim} \quad (2)$$

where the alpha factor, α , depends on the planned operation period, T_{POP} , the operational limiting OP_{Lim} significant wave height, the forecast levels and whether or not meteorologists or measurement equipment are available on site (DNVGL 2016).

Assessment of Operational Limits

Operational limits need to be assessed during planning of marine operations. The limits can be expressed in terms of environmental conditions (sea states, wind, and current conditions) or motions that could be monitored on-board the installation vessels before executing the operation. The operational limits depend on the type of operation and the property of the dynamic system. The operational limits can be used to improve the system performance in the planning phase, that is, to select vessels and equipment, to optimize the procedure, and to propose contingency or mitigation actions. They can also be used together with the weather forecasts to support on-board decision making in the execution phase. Traditionally, operational limits have relied mostly on practical marine operation experiences. However, it is important to quantify the responses (forces, motions) and corresponding operational limits for complicated operations with strict requirements. A systematic method to establish the operational limits is required.

Li (2016) and Guachamin-Acero (2016b) established a general methodology to establish the operational limits (Li 2016; Guachamin-Acero 2016). It includes six main steps, see Fig. 1.

1. Identification of potentially critical events.

Based on the operational procedure, a preliminary selection of activities which could lead to critical events is required. The preliminary selection requires qualitative risk assessment

Marine Operations,

Fig. 1 General methodology to establish the operational limits. (Li 2016)

based on experience, guidelines, and by reviewing of relevant operations.

2. **Numerical modeling of operational activities.** Numerical modeling and analysis of the potential critical events are required to evaluate the dynamic responses of the installation systems. A quantitative assessment of the dynamic responses under reasonable environmental conditions will indicate which response parameters may reach high levels and thus limit the operation.
3. **Identification of critical events and limiting parameters.** By assessment of the dynamic responses, the events governing each offshore activity and leading to failure events are identified. They are identified as critical events, and the governing dynamic responses are defined as limiting parameters.
4. **Calculation of characteristic dynamic responses.** Once the limiting parameter is identified, a characteristic value of its dynamic response needs to be calculated. The dynamic responses should be treated in a probabilistic way to take into account the stochastic nature of the environmental conditions (e.g., wind, wave, and current conditions).
5. **Evaluation of the allowable limits.** The allowable limits are the maximum values that the limiting parameters may reach to remain within acceptable safety margin. It needs to be specified based on safety criteria to avoid structural failure and the exceeding of specified

installation requirements. For events related to structural failure, structural analysis or finite element modeling to determine the strength or the capacity of the structure is normally required to provide the allowable limits.

6. **Assessment of the operational limits.** By comparing the characteristic dynamic responses and their allowable limits for all possible sea states, the allowable sea states at which the responses are less than the allowable limits can be found. These sea states can be transformed into allowable motion responses. In general, both the allowable sea states and responses can be used as operational limits.

This general methodology uses response-based criteria to determine the allowable limits of sea states and to assess the safety of the operation. The operation is considered to be safe if the characteristic value of the governing response is less than the capacity. Often, safety factors need to be considered to take into account the uncertainties associated with the analyses or the data in the assessment of both the load effect and the resistance. Uncertainties on the weather forecasts need to be included by implementing alpha factor. Other uncertainties related to the wave spectra should also be implemented (Guachamin-Acero and Li 2018). This general methodology has been applied in analyses of various marine operations (Li et al. 2016a; Gao et al. 2016; Guachamin-Acero et al. 2017).

Installation Methods for Offshore Wind Turbines

The installation of an offshore wind farm includes the transportation and installation of foundations, turbine components (tower, rotor, and nacelle assembly, RNA), substations, and cables. The most commonly used method for foundation installation is heavy lifting operation using either floating cranes or jack-ups. Turbine components are normally lifted and installed using jack-up vessels in shallow water depths.

A review of the current installation methods for bottom-fixed offshore wind turbine (OWT) foundations, turbine components, as well as floating wind turbines is presented here. Recently developed installation concepts are also discussed.

Installation Methods for Bottom-Fixed Foundations

Methods for installing foundations depend on the foundation type. The most commonly used bottom-fixed foundations include monopiles, gravity-based foundations, jackets, and tripods.

Monopiles

Monopiles are transported either on-board of a barge or an installation vessel or capped and wet towed (Herman 2002). The wet tow of a single floating monopile has been applied during installation of two wind farms (Npower Renewable 2006; Ballast Nedam 2011). The transportation of more than one monopile per trip can be achieved using proper connection between the monopiles.

Installation of monopiles using crane vessels in general includes three main steps: upending, lowering, and hammering operations. A combined wet-tow and upending in water can be performed by lower capacity cranes than those required for transporting and upending on board. However, the upending of long monopiles in water is more weather sensitive than upending on board. Moreover, the verticality of the monopile during hammering operation should also be carefully controlled. Figure 2a shows a monopile lifting operation by the heavy lift vessel (HLV) “Svane.” Li (2016) studied extensively the

monopile lowering operation by considering the nonstationary features of the installation process (Li et al. 2014, 2015, 2016b). The dynamic responses during the hammering process were also investigated (Li et al. 2016a). The allowable sea states in terms of significant wave height (H_s) and wave spectral period (T_p) and the operability at one reference site for the whole monopile installation have been derived (Guachamin-Acero et al. 2016b).

Gravity-Based Foundations

Gravity-based structures (GBS) for wind turbines weigh over 2500 tons. They can either be wet-towed or dry-transported on a barge or an installation vessel. Most of the existing GBS in very shallow waters are dry-transported to the offshore site. Wet-tow can reduce the installation costs by chartering lower capacity lifting vessels. Although the wet-tow method is widely used for transporting gravity-based platforms, it has not been applied for installing GBS of OWTs because their weight is still within the crane capacity of available HLVs. However, if larger GBS are applied for offshore farms in deeper waters, the wet-tow method may be more cost-efficient. Figure 2b displays a lifting operation of a GBS by a HLV.

A novel installation concept was proposed to transport and install a fully assembled gravity-based foundation OWT using double-barge supports and standard tugboats (Wasjø et al. 2013). The concept aimed to reduce the costs by avoiding the use of heavy lift crane vessels. Model tests and numerical studies have been conducted to assess the feasibility of this concept (Bense 2014).

Jackets and Tripods

Jackets and tripods for OWTs can range from 400 to 1000 tons and with a height of 30–90 m in water depth of around 20–70 m. Figure 2c and d shows typical installation activities for jacket and tripod. The jackets can be transported in either an upright or horizontal position depending on the size of the foundations and the available transport barges. The installation of piles could be carried out either after positioning the jackets (*post-piling*) or before jackets installation (*pre-piling*) (LORC 2013).

Marine Operations, Fig. 2 Installation of bottom-fixed OWT foundations. (a) Monopile lifting operation. (Source: <https://www.offshorewind.biz/>), (b) GBS installation.

(Peire et al. 2009), (c) Jacket upending operation. (Source: <http://www.rechargenews.com>), (d) Tripod lifting operation. (Source: <http://www.4coffshore.com/>)

Post-piling is traditionally used in the oil and gas industry and was applied for the jackets in Beatrice wind farm. Experience with pre-piling is limited, but it was first used for the jackets at Alpha Ventus wind farm (Østvik 2010). Pre-piling is considered to be a faster method than post-piling. With pre-piling, smaller vessels can be employed for the piling operation and the HLVs are only required to lift the jackets into the preinstalled piles. With post-piling, the expensive HLVs are used to install both the jacket and the piles. In addition, a considerable amount of steel can be saved using pre-piling because the sleeves for the piles are unnecessary.

Installation Methods for Turbine Components

Transportation and installation methods for turbine components are very different from those for foundations. They must be dry-transported

on-board an installation vessel or a feeding barge. The turbine, particularly the nacelle and the rotor, have sensitive components which only tolerate very limited accelerations during transportation and installation. Moreover, lifting operations are weather-sensitive especially at large lifting heights, and the mating between the components is challenging.

There are many alternatives for turbine installation. Figure 3 shows the commonly used installation strategies. The weight of each component for the NREL 5 MW reference turbine (Jonkman et al. 2009) is included in the figure. The choice of method is related to the vessel size, distance from port to site, size of the wind turbines, and the lifting capacity of the crane. By increasing the amount of onshore assembly, the offshore construction work can be reduced. However, the assembled components reduce the efficiency in

Components and weights	Installation method	Number of lifts					
		1	2	3	4	5	6
2 tower sections:  173.75 ton each	1						
	Lift weight	173.75	173.75	300.5	16.5	16.5	16.5
nacelle:  240 ton	2

hub:  110 ton	3						
	Lift weight	173.75	173.75	240	110		
3 blades:  16.5 ton each	4						
	Lift weight	173.75	173.75	333.5	16.5		
	5						
	Lift weight	347.5	333.5	16.5			
	6						
	Lift weight	697.5					

Marine Operations, Fig. 3 Installation alternatives for turbine components including number of lifts and lift weights. (Kaiser and Snyder 2011)

using the deck space and increase the number of trips for transportation when installing a large wind farm. In addition, the weight of the fully assembled turbine with the large lift height requires very large and expensive crane vessels (Ku and Roh 2014).

Among the methods for blade installation, single blade installation is most frequently used for offshore installation in recent years, due to small deck space requirement and flexible blade orientations during installation (Ahn et al. 2017).

During the installation process, the blade is lifted and installed in a feathered position, which is kept during the whole installation operation (Kuijken 2015). Recently, extensive studies on a single blade installation have been carried out. (Zhao et al. 2018a, b) developed an integrated aero-hydro-soil-elastic-mechanical tool for simulating installation of a single blade for wind turbines. (Jiang et al. 2018a) studied the final blade installation phase onto a monopile wind turbine. The effects of mean wind speed, wind turbulence,

significant wave height, wave spectrum peak period, wind-wave misalignment, and water depth on the blade installation were evaluated. Moreover, some studies have been focusing on developing active control schemes to control the tugger lines used for blade installation, with the purpose to increase the weather window for the final mating phase between the blade root and the hub (Ren et al. 2018a, b).

In addition to the methods shown in Fig. 3, a few innovative concepts to install fully assembled tower and RNA have been proposed. Sarkar and Gudmestad (2013) designed a floating substructure to transport the fully assembled structure, but the concept was only applicable for telescopic tower (Sarkar and Gudmestad 2013). Guachamin Acero et al. (2016a) proposed a new concept based on the principle of the inverted pendulum (Guachamin Acero et al. 2016a). The feasibility of this installation concept was assessed by numerical analyses.

Installation Methods for Floating Wind Turbines

Installation methods for floating wind turbines are quite different from those for bottom-fixed wind turbines due to larger water depth of the installation site. For turbine installation in shallow water, jack-up vessels are normally used to provide stable platform for lifting and offshore bolting, which could hardly be carried out by a floating vessel with motions in six degrees of freedom. However, for deep waters, if onshore assemble is chosen, the installation can only be performed by floating vessels, and it was proven to be difficult and costly.

The installation method differs with different floating structures. The Hywind Scotland, which was the first offshore floating wind farm, applies a spar-type floating wind turbine. The spar buoy was dry-towed in a horizontal configuration using a transportation vessel and upended to a vertical position by ballasting the spar. The tower, nacelle, and blades were preassembled onshore and installed by a single lift using a large heavy lift vessel. Both the upending of the spar and the mating between the tower and the spar buoy are critical operations. In order to

increase the operability, the installations were done at a well-sheltered location in deep water. Then, the fully assembled floating unit was towed to the site and hooked up to the mooring system (Lien 2016).

The installation of Windfloat, on the other hand, was the first offshore wind turbine to be deployed without the use of any offshore heavy lift vessel. Due to the shallow draft of the semi-submersible foundation, the turbine could be fully assembled onshore prior to the unit being towed offshore (Roddier et al. 2010). In this way, all the weather-sensitive lifting operations can be carried out onshore, which could reduce the installation costly significantly when installing a large number of wind turbines with this type of foundations. Once at shore, the floating structure was hooked up to the preinstalled mooring system.

In order to reduce the installation cost to make floating wind turbine more cost-effective, innovative installation strategies are required. In the Hywind installation challenge campaign (Equinor 2018), and among the proposed innovative installation concepts, there is a tendency to favor novel installation vessels and facilities to reduce offshore lifts and operation time. A novel wind turbine installation concept was proposed to use a catamaran installation vessel for installations of fully assembled OWTs (Jiang et al. 2018b, c). This concept avoids extremely weather-sensitive high lifts from a floating vessel by carrying the wind turbine on the catamaran and a gripper device. This installation method was deemed to be suitable for both offshore bottom-fixed or floating foundations.

Marine Protected Areas in Areas Beyond National Jurisdiction

Dong Sun¹ and Miao Zhuang Zheng²

¹Key Laboratory of Marine Ecosystem Dynamics, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, China

²China Institute for Marine Affairs, Ministry of Natural Resources, Beijing, China

Synonyms

[Areas beyond national jurisdiction \(ABNJ\)](#); [Marine protected area \(MPA\)](#); [Marine protected areas in areas beyond national jurisdiction \(MPA in ABNJ\)](#)

Definition

A marine protected area (MPA) is “a clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values” (Muraki Gottlieb et al. 2018). If a part of or whole MPA is located on the ABNJ, then we call it “marine protected areas in areas beyond national jurisdiction (MPA in ABNJ).” MPAs do not mean absolutely no fishing or other human activities; in fact, most MPAs in the world are multipurpose areas. The no-fishing MPAs are often referred to as “no-take areas.”

Scientific Fundamentals

Areas beyond the national jurisdiction (ABNJ) amount to approximately 61% of the oceans, 44% of the surface of the Earth, and 65% of the volume of the biosphere but remain the least protected space on the planet (Gjerde et al. 2016). However, these areas are increasingly under threat from anthropogenic activities such as pollution, overfishing, mining, and geoengineering. At the UN Conference on Sustainable Development in Rio de Janeiro in June 2012, the world’s political leaders committed to the conservation and sustainable use of marine biological diversity in areas beyond national jurisdiction (ABNJ) (UN 2012). After that, the General Assembly decided to convene an Intergovernmental Conference to elaborate the text of an international legally binding instrument under the United Nations Convention on the Law of the Sea (UNCLOS) on the conservation and sustainable use of marine biological diversity of areas beyond national jurisdiction. The Conference will meet for four sessions. The first three sessions were conducted in 2018 to 2019. By decision 74/543 of March 11, 2020, the General Assembly decided to postpone the fourth session of the conference to the earliest possible available date to be decided by the General Assembly (UN 2020) (<https://www.un.org/bbnj/>). After

Marine Protected Areas in Areas Beyond National Jurisdiction, Fig. 1 Diagram of maritime zones by UNCLOS

this, a new regime about the marine protected areas in ABNJ will be expected.

ABNJ legally comprise the “high seas,” which indicated the waters beyond the exclusive economic zones (EEZ) of national jurisdiction, and the “international seabed area” (“the Area”), which indicated the seabed, the ocean floor, and subsoil thereof beyond national jurisdiction (UNCLOS Articles 1 and 86) (Fig. 1). If a part of or whole MPA is located on the ABNJ, then we call it “MPA in ABNJ.”

Objectives of Establishing MPAs in ABNJ

For the past few decade years, the ABNJ were under increasing and intensive threats from human activities, such as overfishing, pollution, maritime shipping, and climate change. Besides, it will also be strongly threatened by potential deep-sea resource exploitation, including oil, gas, and metallic ores, in the future (Sharma 2015; Gjerde et al. 2016). These issues not only threaten the biodiversity in ABNJ (Oleary et al. 2020) but also depress the ecosystem function and service in

these areas (Worm et al. 2006; Rogers et al. 2014) (Table 1).

MPAs are widely considered as an important tool for the conservation of biological diversity and marine ecosystems in the past several decade years (Lester et al. 2009). By the end of August 2020, 17,237 MPAs were established in the world, and they covered near 27 million square kilometers in area, about 7.45% area of world’s oceans. However, only less than one in a thousand MPAs were established in ABNJ (Smith and Jabour 2018). It meant that the ABNJ were largely under absolutely unprotected conditions (Gjerde et al. 2016).

The Potential Cost of MPAs in ABNJ

The establishment of MPAs in ABNJ, especially the “no-take” MPAs, could be also with some cost, at least in short term. First, fisheries data show that 6% of global fish catch is obtained in ABNJ (www.seaaroundus.org/data/#/global). Thus, if the current and potential fishing areas in ABNJ are protected and all forms of fishing are strictly prohibited in these areas, the global supply of fish will be

Marine Protected Areas in Areas Beyond National Jurisdiction, Table 1 The current and potential threats to biodiversity and ecosystems in ABNJ, from human activities and climate change

Activity	Impacts or threats to biodiversity and ecosystems in ABNJ
Fishing	Fishing is the most significant direct threat to biodiversity in ABNJ now and also with high and widespread environmental impacts to habitats and ecosystems (Pauly et al. 2005)
Maritime shipping	Given the large spatial extent of shipping activities, environmental impacts are likely to be high. For example, anthropogenic noise from ship was considered to be with great impacts on marine life (Nowacek et al. 2010; Williams et al. 2015)
Climate change and associated effects	Ocean ecosystems are already experiencing significant change mainly because of ocean acidification, hypoxia, and warming, and changes will continue to extend across ABNJ in the future (Doney et al. 2012)
Land-based pollution	Environmental impacts from land-based pollution are high and affect all aspects of marine life, even in deep seafloor (Van Cauwenberghe et al. 2013)
Deep-sea mining	Environmental impacts are likely to be high and broadly distributed and impact the entire seabed to surface ecosystem. Although deep-sea mining is not a current threat in “the area,” it is widely considered as a reality in the near future (Durden et al. 2018)
Oil and gas exploration and exploitation	The local and regional impacts are experienced which can have high negative environmental impacts to the entire seabed to surface ecosystem (Gray et al. 1999). No offshore oil and gas drilling operations currently take place in ABNJ, but it could happen accompanied by shortage of energy and technological advancement in the future
Bioprospecting for marine genetic resources and scientific research	Bioprospecting and scientific research have a small scope and temporal and spatial footprint. Thus, the environmental impacts to biodiversity and ecosystems are considered to be weak
Aquaculture	Currently, aquaculture activities are mainly concentrated near to shore in EEZs, and the expansion of aquaculture offshore is likely to be contained within areas of national jurisdiction in the future. But, some ecological and environmental impacts of aquaculture activities are still largely unknown, such non-native species escapes from aquaculture (Ju et al. 2020)
Renewable energy	Currently, engineering construction of renewable energy in marine remains in EEZs, and the expansion is likely to be contained within areas of national jurisdiction in the future
Military	Because of its secrecy, less data are able to be used to evaluate the environmental impacts on marine biodiversity and ecosystems. However, a limited amount of evidence showed the potential impact from military, especially the underwater noise, could not be ignored (Tyack et al. 2011; Morell 2015)
Submarine cables and pipelines	The submarine cables only cover 0.00002% of seabed in ABNJ, and no significant and widespread environmental impacts were found (Taormina et al. 2018). The oil and gas pipelines are considered to be with great potential environmental impacts in offshore and continental shelf (Dey et al. 2004), and it was unlikely given the lack of oil and gas exploration and exploitation in deep sea of ABNJ

Adapted from Oleary et al. (2020)

reduced, especially the tunas and squids (Sala et al. 2018). Second, a large proportion of maritime shipping routes are located on the ABNJ. Environmental protection terms of MPAs in ABNJ, such as

control of air pollution emissions and underwater noise levels of ships in the protected area, will inevitably increase the costs of maritime shipping (Gallucci 2018). Third, some underwater

engineering, such as laying or maintaining of submarine cables, pipelines, and other facilities, may face stricter environmental impact assessment.

Key Applications

The Current Status of MPAs in ABNJ

MPAs in ABNJ: Lessons from Two High Seas Regimes
Although there is still much debate about the details, establishing a network of MPAs in

ABNJ is viewed as an important measure to protect marine biodiversity and widely accepted (Smith and Jabour 2018). To date, 13 MPAs have been established in ABNJ: 2 in the Southern Ocean, 10 in the North-East Atlantic region, and 1 in the Mediterranean Sea (Table 2).

The Future Harder Task

The world’s ocean represents the largest ecosystem on Earth comprising 1.3 billion km³ of water. Considering the strong and widespread

Marine Protected Areas in Areas Beyond National Jurisdiction, Table 2 Thirteen MPAs in ABNJ (including wholly or partly) have been established to date

	Name of MPAs	Location	Remarks
1.	South Orkney Islands southern shelf MPA	Southern Ocean	It is the world’s first wholly high-seas MPA (in 2009). And it is also the first no-take marine reserve in the CCAMLR’s network of Southern Ocean MPAs
2.	Ross Sea region MPA	Antarctica and Southern Ocean	The world’s largest MPAs in ABNJ (It covers 1.55 million square kilometers, of which 72% is “no-take” area.). It is also in the CCAMLR’s network of Southern Ocean MPAs
3.	Pelagos Sanctuary	Mediterranean Sea	Maybe, it is the first MPAs in ABNJ (in 2002), because it currently is located in part on the high seas. The Sanctuary has been designated and is jointly managed by France, Italy, and Monaco
4.	Charlie-Gibbs South MPA	North-East Atlantic Ocean	Entirely within ABNJ. The seabed, the subsoil, and the water column are protected by all OSPAR CPs
5.	Milne Seamount Complex MPA		
6.	Mid-Atlantic Ridge north of the Azores High Seas MPA		
7.	Altair Seamount High Seas MPA		
8.	Antialtair High Seas MPA		These four MPAs are located within an area subject to a submission by Portugal to the UN CLCS for an ECS. Portugal has expressed the intention to assume the responsibility to take measures for the protection of the seabed and the subsoil within these areas. Upon invitation by Portugal, the OSPAR Commission agreed to collectively protect the water column of these MPAs
9.	Josephine Seamount High Seas MPA		
10.	Charlie-Gibbs North High Seas MPA		
11.	Rainbow Hydrothermal Vent Field SAC		This MPA is partly situated within an area subject to a submission by Iceland to the UN CLCS for an ECS. The water column is protected collectively by all CPs. The seabed and the subsoil remain unprotected
12.	Hatton Bank		
13.	Hatton-Rockall Basin		
			These MPAs are situated within areas subject to a submission by a CP to the UN CLCS for an ECS. The seabed and subsoil of these sites are protected by the respective CP, while the water column remains unprotected

ECS: Extended Continental Shelf
CP: Contracting Party of OSPAR

connectivity of marine ecosystem and the multiple threats on marine biodiversity, more MPAs in ABNJ are absolutely necessary in the future. However, there are still some barriers about more MPAs in ABNJ. First, recent study showed that 54% of the present fishing grounds in ABNJ would be unprofitable at current fishing rates, if the subsidies from governments disappear. The first five countries which provide largest subsidies are Japan, Spain, China, South Korea, and the United States. All of these countries also organize the largest high-seas fishing fleet in the world (Sala et al. 2018). Thus, we must more rationally regulate high-seas fishery subsidies and management, along with the process of establishing more MPAs in ABNJ. Second, several independent frameworks to manage and protect the marine ecosystems in ABNJ have already existed. For example, fishing is managed regionally by some regional fishery management organizations (RFMOs), shipping is managed by various conventions under the International Maritime Organization (IMO), and deep-sea mining in “the areas” is managed by the International Seabed Authority (ISA) (Altwater et al. 2019). Nonetheless, cooperation and coordination among these different frameworks are largely limited, which challenges the protection of marine ecosystems in ABNJ. Third, our understanding of deep-sea biodiversity and deep-sea ecosystem functions is far from enough until now (Appeltans et al. 2012, Thurber et al. 2013). This gap in knowledge is a great barrier in establishing of MPAs in ABNJ. To overcome it, more new methods, such as data-driven planning tools (Visalli et al. 2020), are needed to instructing the planning model for MPAs.

Mega-Float

Kazuhiro Iijima
Department of Naval Architecture and Ocean
Engineering, Osaka University, Osaka, Japan

Synonyms

[Mobile offshore base \(MOB\)](#); [Very large floating structures \(VLFS\)](#)

Definition

Mega-Float is a type of VLFS whose concept was developed, particularly in Japan. Mega-Float

originates from a coined word meaning “Mega” (huge) + “Float” (floating structure). It is sometimes referred to as “Mega-Float.” Technological Research Association of Mega-Float (TRAM) in Japan initiated the project with the same name “Mega-Float” in the 1990s. Mega-Float also denotes such a pontoon type very large floating structures (VLFS) for ocean space utilization as studied and developed by TRAM. The objective of Mega-Float is ocean space utilization, being deployed for long years in a sheltered sea area, which is contrary to Mobile Offshore Base (MOB) deployed in rather offshore sea area for sometimes tentative use. The Mega-Float project by TRAM started in 1995 and continued for 6 years. The focus of Phase I project (1995–1996) was on the development of fundamental technologies such as design and construction of VLFS while it was on the demonstration as an airport in Phase II (1997–2001). A VLFS with the length 1000 m was designed, constructed, and tested to demonstrate its function as a floating runway in Phase II project. This VLFS was regarded as the largest man-made floating island and certified in 1999 by the Guinness World Records. A semi-submersible type Mega-Float (SSMF) for offshore deep waters was also studied by TRAM. However, the investigations into SSMF were limited. This article mainly overviews the Mega-Float concept and the technologies developed in Mega-Float projects that were carried out in Japan between 1995 and 2001. Reference may also be made to the literatures such as Suzuki (2005) and Fujikubo and Suzuki (2015).

Scientific Fundamentals

Mega-Float Concept

The concept of Mega-Float developed by TRAM is illustrated in Fig. 1. Mega-Float is installed in a sheltered sea area (such as bay), and it consists of a large floating structure and a mooring system. An access from land can be a part of it. The breakwater to protect Mega-Float from severe waves is also constructed around it if necessary. The structure is constructed by the at-sea joining

Mega-Float, Fig. 1 Conceptual sketch of Mega-Float system (Taken and reproduced from SRCJ web page)

and welding of the steel structural units that have been pre-constructed in shipyards. It can create artificial ocean space on the sea, of an arbitrary shape fitting for its function.

The advantages of Mega-Float over the land reclamation may be summarized below.

- Mega-Float can be installed in the sea area with soft ground and/or deep waters.
- Mega-Float can comply with high tidal variation
- Mega-Float is extensible, movable, and removal. Design has a high flexibility.
- Mega-Float gives less impact to marine environments.
- Mega-Float construction costs lower and is made in a shorter period.
- Mega-Float is stronger against ground motions in earthquakes.

Design Technology of Mega-Float

Numerical simulation methods had to be developed for the design since Mega-Float was an unprecedented structure and the design need to be proceeded together with the numerical analysis (Design-by-Analysis). The key issue is hydroelasticity. Several hydroelasticity codes for VLFS have been developed and cross-validated in the Mega-Float project since the design of VLFS must be carried out together with the numerical simulation tool which takes account of the hydroelasticity of Mega-Float. Most of the codes are based on the diffraction theory in frequency domain. Structural modeling is different among the codes; some used beam elements, while the other plate theory, shell FEM, etc.

Other technological issues have also been investigated. They include the optimum arrangement of mooring system, and safety evaluation in the extreme event and catastrophic event (drop object, collision, earthquakes, damaged condition). Hydraulic tests using scaled models are also performed to validate the numerical simulations.

Environmental impact has also been investigated in terms of flow blockage, salinity change, and temperature distribution. The impact on ecosystem around and below Mega-Float is clarified by the numerical simulations and field measurement in Mega-Float project. The results indicate only little effect, except for a small reduction in dissolved oxygen adjacent to Mega-Float.

Construction Technology of Mega-Float

Mega-Float is finally assembled and constructed at sea. The construction process is as follows (Yamashita et al. 2007; see Fig. 2):

- Unit structures (modules) are pre-fabricated/ built in shipyards. The maximum size of the unit structure depends on the size of the dock, however, typically ranging from 100 m to 300 m in length. The ship-building technologies can be applied.
- The units are towed out from the dock to the site by using towing boats. The relative motion among the units are restrained and stiffened gradually by using mechanical joints and finally welded together. When joining two structures, at least, one of the two is moored to the “dolphin.”

Mega-Float, Fig. 2 Construction process of Mega-Float

- At the beginning of the restraining process, mechanical devices such as jacks, turnbuckles and wooden wedges are used to reduce the relative motion. In the later stage, the degree of restraints is strengthened. Steel strong-backs and fitting pieces are welded to the units, in order to conduct the welding works with good quality between the two units.
- For the underwater welding, a specially designed chamber attached to the bottom of a hold compartment is drained of the water by using blowers to pump in the compressed air.
- The above process is repeated until Mega-Float is formed at sea.
- Mega-Float is moored to the mooring facility in and after the construction process.
- The thermal deformation to the sunlight and welding deformation are to be considered in the fabrication and construction.

Mooring Technology of Mega-Float

The mooring system of Mega-Float may be selected and designed from various options depending on the water depth and environmental conditions. For deep waters, conventional catenary mooring system may be adopted. For shallow to mid-water depth (20–40 m), the mooring system consisting of steel pile/jacket structure and fender is typically adopted. The marine jacket for mooring is sometimes called “dolphin.” The dolphin is piled to sea floor. Mega-Float is equipped with steel “arms” to hold the dolphin. Between the arms and dolphin, the fenders are inserted for shock-absorbing the contact loads between the

dolphin and Mega-Float. The fender is a rubber-made structure, with the diameter 1–2 m, which can bear the large drift force on Mega-Float due to waves, wind, and current. It is attached either to the dolphin or the floating structure side.

Figure 3 shows a sample of dolphin-fender system used for Mega-Float (left) and the non-linear reaction force characteristics of the mooring system (right). Normally, there is a gap between the fender and Mega-Float, of few tens of centimeters as the excess play. Within the excess play, Mega-Float moves freely. No reaction force is supplied in this region. When the contact starts between the fender and the float, or the fender or the dolphin, the fender gives the reaction force to the structure in proportion to the contact displacement. When the reaction force reaches a certain level to the increased displacement, the fender undergoes buckling of the rubber. Then, the reaction force becomes almost constant to the further increase of displacement. This reaction force characteristics are beneficial; the mooring system allows large displacement and dissipate the energy, while the constant load does not damage the dolphin structure due to the further increase of the reaction force.

Historical/Societal Background of Mega-Float

Japan is an island country surrounded by seas. About 80% of the land is mountainous, while the rest of 20% is used as the industrial or city areas, and they are concentrated near the shorelines. Ocean space utilization has been considered necessary, particularly in the metropolitan areas.

Mega-Float, Fig. 3 Mooring system for Mega-Float and its mechanical characteristics. (Reproduction from Iijima et al. 2002)

However, the seas around the metropolitan areas that had good conditions for reclamation in terms of water depth and soil condition was already reclaimed. In the 1970s, the feasibility of a floating airport was investigated for the phase 1 construction of Kansai airport using a semisubmersible type VLFS, as a gateway to Osaka (Takarada 1982). Even though the proposal of building the floating runway for Kansai airport was not accepted, then the ship-builders of Japan and academia started to pursue the technologies for VLFS. With these backgrounds, TRAM was founded in 1995 and started their investigations (Okamura 2004).

Key Applications

Mega-Float Phase I Project

TRAM was comprised of 17 leading shipbuilding companies and steel companies in Japan and was founded in April, 1995, on the initiative of Japanese government. The research activities were carried out in Phase I and Phase II projects. Phase I project focused on the development of the fundamental technologies of design and construction. Phase II project focused on the demonstration (Technical Research Association of Mega-Float 1999, 2000, 2001; Sato and Inoue 2003; Yoshida 2003).

The main aims of Phase I were (1) establishment of technologies for design, (2) establishment of technologies for the construction, (3) evaluation

of impact on the upper structures, (4) establishment of long-term durability, and (5) establishment of evaluation method for environmental impact. In Phase I project, the application of Mega-Float was not specified to the airport. The construction technology as explained in the “Construction Method of Mega-Float” section was pursued.

For establishing the joining technology, a small prototype Mega-Float structure with the length 300 m, the width 60 m, and the depth 2 m was constructed as sea off Yokosuka, Japan. The Mega-Float consisted of nine units, each of which had the size 100 m $\times$ 20 m. For the welding technique development, the welding shrinkage and deformation were measured in the at-sea test. The dry welding using the drainage system was found to be effective in securing the welding quality rather than wet welding. The small prototype Mega-Float in Phase I was later reinforced and extended to the Mega-Float with the length 1000 m.

Mega-Float Phase II Project

The application as an airport, whether or not airplanes can land and take-off, was questioned for Phase II project. TRAM designed and constructed a floating runway (see Fig. 4) using Mega-Float technologies off Yokosuka (the same site as Phase I). The size of the structure was 1000 m in length, 60 m in breadth (121 m partially), and 1 m in draft. The structural depth was 3 m. The size was equivalent to the existing small commuter airport. The frequency domain simulation was extended to

Mega-Float, Fig. 4 1000 m class Mega-Float off Yokosuka, Mega-Float Phase II project (By the courtesy of Shipbuilding Research Centre of Japan)

M

1000 m airport case and used for checking its function. Time domain simulation was developed, and the taking-off and landing of an airplane was simulated for safety.

For functionality check as an airport, several considerations on the facilities were further necessary. They include the following:

- The dolphin top must be below the line extending at a predetermined angle from the end of the runway known as “Obstacle Limitation Surface.” Low-headed dolphin for mooring system was developed.
- Approach lights arranged on fixed piles and Mega-Float must be in line within a certain allowance to guide the airplane landing.
- The surface of the steel Mega-Float structure which has dynamic deformation to waves need to be paved with asphalts. Pavement method was investigated, and durability test was performed.
- Navigation equipment such as “Instrumental Landing System (ILS),” “Precision Approach Pass Indicator (PAPI),” and “Future Air Navigation System (SAS)” must function on Mega-Float.

After the completion of the at-sea tests, the Mega-Float structure in Phase II was dismantled (actually, dismantling works were part of the research activities) and removed from the test site. Some parts were reused as “Data Backup Base” in case of disaster, “World Cup Mega-park,” and marine fishery parks. TRAM was dissolved in 2001, and the activities were succeeded by the Shipbuilding Research Centre of Japan (SRC).

Haneda Airport Extension Bid

Haneda airport located in Tokyo Bay is famous as a gateway to Tokyo and one of the world largest and busiest airports. The Japanese Government

decided to construct the fourth runway to Haneda airport which was planned to be in operation in 2009. The fourth runway was to be constructed near the river mouth of Tama River. There were three concepts proposed for the runway: Mega-Float, pile-supported wharf, and a hybrid of reclamation and pile-supported wharf. The Shipbuilders' Association of Japan bid for the construction and proposed the Mega-Float with the length 4000 m (Sato and Inoue 2003; Yoshida 2003). The design service life was 100 years. The design wave height at the site was 2.3 m in significant wave height and the significant wave period 5 s for operation condition. Even for the storm condition, the significant wave height was 3.7 m considering a storm with 200 years of return period. The technical committee to the fourth runway of Haneda airport concluded that all of the three construction proposals have the possibility of being adopted with not serious technical defects. Finally, the consortium for the hybrid of reclamation and pile-supported wharf made a successful bid.

Other Applications

Mega-Float may be used as airport, container terminal, recreation spot, emergency rescue base, storage facility, marine renewable energy platform, solar energy platform, etc. There are various application proposals for these applications. However, no Mega-Floats have been realized so far, except the ones in the Mega-Float projects. Recently, Mega-Float seems to be re-gaining attentions by the engineers. The development of autonomous ship, hydrogen-driven ships, etc. may imply a need for the offshore base, or an ocean space in deeper waters. Mega-Float may also be utilized in such a context.

Meteorological Monitoring and Measurement Buoy

Wanan Sheng

SW MARE Marine Technology and Consultation,
Cork, Ireland

Definition

Meteorological monitoring and measurement buoys (aka weather buoys) are the buoys to measure parameters for monitoring and weather forecasting. The measurements include air temperature above the ocean surface; wind speed and direction; barometric pressure; sea water temperature and salinity; wave height, period and direction; and current etc. The weather buoys can be an important part of the global weather monitoring and prediction system (see the ocean data buoy in Fig. 1).

Generally, raw data can be processed and logged on board of the buoy and then transmitted via radio, cellular, or satellite communications to meteorological centers for use in weather forecasting and climate study.

Scientific Fundamentals

Meteorological buoys are instruments which collect weather and ocean data within the world's oceans, as well as aid during emergency response to chemical spills, legal proceedings, and engineering design. Moored buoys have been in use since 1951, while drifting buoys have been used

since 1979. Moored buoys are connected with the ocean bottom using either chains, nylon, or buoyant polypropylene. Different types of weather buoys are used by different organizations (see Figs. 2 and 3).

The first known proposal for surface weather observations at sea occurred in connection with aviation in August 1927, and starting in 1939, United States Coast Guard vessels were being used as weather ships to protect transatlantic air commerce.

During World War II The German Navy deployed weather buoys (*Wetterfunkgerät See* – WFS) at fifteen fixed positions in the North Atlantic and Barents Sea. They were launched from U-boats into a maximum depth of ocean of 1000 fathoms (1,800 m), limited by the length of the anchor cable. Overall height of the body was 10.5 m (of which most was submerged), surmounted by a mast and extendible aerial of 9 m. Data (air and water temperature, atmospheric pressure and relative humidity) were encoded and transmitted four times a day. When the batteries (high voltage dry-cells for the valves, and nickel-iron for other power and to raise and lower the aerial mast) were exhausted, after about 8–10 weeks, the unit self-destructed.

The Navy Oceanographic Meteorological Automatic Device (NOMAD) buoy's 6-m (Fig. 4) hull was originally designed in the 1940s for the United States Navy's offshore data collection program. The United States Navy tested marine automatic weather stations for hurricane conditions between 1956 and 1958, though radio transmission range and battery life was limited. Between 1951 and 1970, a total of 21 NOMAD buoys were built and deployed at sea. Since the 1970s, weather buoy use has superseded the role of weather ships, as they are cheaper to operate and maintain. The earliest reported use of drifting buoys was to study the behaviour of ocean currents within the Sargasso Sea in 1972 and 1973. Drifting buoys have been used increasingly since 1979, and as of 2005, 1250 drifting buoys roamed the Earth's oceans.

Between 1985 and 1994, an extensive array of moored and drifting buoys was deployed across the equatorial Pacific Ocean to monitor and help

Meteorological Monitoring and Measurement Buoy, Fig. 3 Weather buoy operated by the National Data Buoy Center

Meteorological Monitoring and Measurement Buoy, Fig. 4 A 6-m NOMAD

predict the El Niño phenomenon. Hurricane Katrina capsized a 10 m buoy for the first time in the history of the National Data Buoy Center (NDBC) on August 28, 2005. On June 13, 2006, drifting buoy 26,028 ended its long-term data collection of sea surface temperature after transmitting for 10 years, 4 months, and 16 days, which is the longest known data collection time for any drifting buoy. The first weather buoy in the Southern Ocean was deployed by the Integrated Marine Observing System (IMOS) on March 17, 2010.

Key Applications

Measurements

Weather buoys, like other types of weather stations, measure the parameters that the conventional weather station measures, including:

- Air temperature above the ocean surface
- Wind speed (steady and gusting)
- Wind direction
- Barometric pressure

and unlike the conventional land weather stations, they measure more oceanographic parameters, including:

- Measure sea water temperature
- Sea water salinity density
- Wave height, and dominant wave period and wave direction
- Ocean/tidal current

Raw data is processed and can be logged on board the buoy and then transmitted via radio, cellular, or satellite communications to meteorological centers for use in weather forecasting and climate study.

Types of Buoys

Moored Buoys

Weather buoys range in diameter from 1.5–12 m (Fig. 5). Those that are placed in shallow waters are smaller in size and moored using only chains, while those in deeper waters use a combination of chains, nylon, and buoyant polypropylene. Since they do not have direct navigational significance, moored weather buoys are classed as special marks under the IALA scheme, are coloured yellow, and display a yellow flashing light at night.

Discus buoys are large round and moored in deep ocean locations, with a diameter of 10–12 m. The aluminum 3-m (10 ft) buoy is a very rugged meteorological ocean platform that has long-term survivability. The expected service life of the 3-m (10 ft) platform is in excess of 20 years and properly maintained; these buoys have not been retired due to corrosion. The NOMAD is a unique moored aluminum environmental monitoring buoy designed for deployments in extreme conditions near the coast and across the Great Lakes. NOMADs moored off the Atlantic Canadian coast commonly experience winter storms with maximum wave heights approaching 20 m (66 ft) into the Gulf of Maine.

Drifting Buoys

Drifting buoys are smaller than their moored counterparts, measuring 30–40 cm in diameter.

Meteorological Monitoring and Measurement Buoy, Fig. 5 Weather buoy operated by the National Data Buoy Center (NDBC)

They are made of plastic or fiberglass and tend to be either bicolored, with white on one half and another color on the other half of the float, or solidly black or blue (Fig. 6). It measures a smaller subset of meteorological variables when compared to its moored counterpart, with a barometer measuring pressure in a tube on its top. They have a thermistor (metallic thermometer) on its base, and an underwater drogue, or sea anchor, located 15 m below the ocean surface connected with the buoy by a long, thin tether.

Many different drifting buoys exist around the world that vary in design and the location of reliable temperature sensors varies. These measurements are beamed to satellites for automated and immediate data distribution. Other than their use as a source of meteorological data, their data is used within research programs, emergency response to chemical spills, legal proceedings, and engineering design. Moored weather buoys can also act as a navigational aid, like other types of buoys.

Meteorological Monitoring and Measurement Buoy, Fig. 6 Drifting buoy

TAO Buoy/Global Tropical Moored Buoy Array

The TAO/TRITON Array was designed to better understand and predict climate variations related to El Niño and the Southern Oscillation

(ENSO). ENSO, the warm phase of which we refer to as El Niño and the cold phase La Niña, represents the strongest year-to-year climate fluctuation on the planet. ENSO events significantly disrupt normal patterns of weather

variability, affecting agriculture, transportation, resource management, energy production, and the lives of millions of people around the globe. ENSO also affects Pacific marine ecosystems and commercially valuable fish stocks such as tuna and anchovy. The project was motivated by the 1982–1983 El Niño event, and it took over the 10 year period 1985–1994 to deploy the buoys (Fig. 7), and the full TAO/TRITON system was built (Fig. 8) and is presently supported by the USA (NOAA/National Weather Service/National Data Buoy Center) and Japan (Japan Agency for Marine-Earth Science and Technology).

The TAO/TRITON array was extended to the Global Tropical Moored Buoy Array (GTMBA, see Fig. 9) after mid-1990, with the additions of the Prediction and Research Moored Array in the Tropical Atlantic (PIRATA), and the Research Moored Array for African-Asian-Australian Monsoon Analysis and Prediction (RAMA) in the Indian Ocean (McPhaden et al. 2009). Now the GTMBA is a global system with its interest spanning intraseasonal-to-decadal and longer timescales on global basis, including:

- El Niño/Southern Oscillation and its decadal modulation in the Pacific
- The meridional gradient mode and equatorial warm events in the Atlantic

Definition

Plastics are polymers, which are chains of molecules derived from small monomer molecules that are extracted from fossil origin (crude oil, gas, etc.), renewable (sugarcane, starch, vegetable oils, etc.) or even mineral base (salt). Microplastics are usually defined as plastic fragments with sizes less than 5 mm.

Scientific Fundamentals

Plastic materials have been widely used in many applications since 1970. The common types of plastics include polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinylchloride (PVC), and polyethylene terephthalate (PET) (Table 1). The global production of plastics has increased rapidly over the past 60 years, reaching almost

Microplastics, Table 1 Plastic types and examples of items commonly found in marine debris

Type of polymer	Common examples of marine debris	Specific density
Polyethylene (PE)	Plastic bags, bottles, gear, cages, and pipes for fish farming	0.91–0.94
Polyethylene terephthalate (PET)	Bottles, strapping, gear	1.34–1.39
Polyvinyl chloride (PVC)	Film, pipe, plumbing pieces, containers, buoys	1.16–1.30
Polypropylene (PP)	Rope, bottle caps, gear, strapping, drinking straws	0.90–0.92
Polystyrene (PS)	Disposable cutlery, utensils, containers, packaging	1.04–1.09
Expansive polystyrene (EPS)	Bait boxes, floats, cups, expanded packaging	0.01–1.05
Acrylonitrile butadiene styrene (ABS)	Electronics and electrics, car interior	1.03–1.11
Polymethyl methacrylate (PMMA)	Architecture, instrument and meter parts, automobile lamp, optical lens, transparent pipe	1.15–1.19
Polyamide or nylon (PA)	Gear, fish farming nets, rope, toothbrushes	1.13–1.15
Polyurethanes (PU)	Packing of fragile goods, aviation, aerospace, automobile manufacturing, liquefied natural gas transport vehicle (ship) manufacturing	1.2–1.25
High density polyethylene (HDPE)	Cleaning product	0.91–0.94
Low density polyethylene (LDPE)	Preservative film	0.94–0.98

Microplastics, Fig. 1 Overview of relevant size ranges for plastic particles

360 million tons in 2018 (PlasticsEurope 2019). However, due to improper plastic disposal across the world, the majority of the plastic litter ends up in marine ecosystems transported via wind, river flow, and effluent discharge from sewage treatment plants. This results in global plastic pollution, particularly in estuarine and marine environments. Plastics in the sea are exposed to ultraviolet (UV) radiation, heat, oxidation, biodegradation, and mechanical disruption and eventually disintegrate into small debris (Shim et al. 2017). Microplastics are widely defined as synthetic organic polymers with an upper size limit of 5 mm (Fig. 1) (Lusher et al. 2013; Zhang et al. 2020), which are derived from the polymerization of monomers extracted from oil or gas (Thompson et al. 2009). These microplastics can be divided

into two categories according to their sources: secondary microplastics, as described above, and primary microplastics. The latter are produced intentionally as microbeads, microfibers, and in other forms (Fig. 2) (Dris et al. 2016) for specific domestic and industrial applications.

Since the 1940s, when plastics were mass-produced, the volume of plastics has increased rapidly. Consequently, the amount of plastic debris entering the marine environment rose in parallel with rates of production. Microplastics have been detected in aquatic systems almost all over the world, including freshwaters, oceans, polar environments, and even pristine mountain lakes or beaches of remote and unpopulated islands (Kettner et al. 2017). When one looks at vertical distribution, microplastics exist in bottom

Microplastics, Fig. 2 Microplastic particles with different shapes

sediments (including abyssal and hadal deep-sea sediment), benthic zone of water mass, water columns, surface waters, and beaches. Numerous investigations have shown that microplastics have the highest abundance in sediment sample, and the values of abundances range from 1.3 to more than 3300 items kg^{-1} dry sediment. However, the abundances of microplastics in surface waters are some orders of magnitude smaller, and the values of abundances range from 10^{-5} to 10^5 item/ m^3 . Meanwhile, the distribution shows distinct geographical variations. The factors affecting the transportation and distribution include large-scale forces currents driven by wind, ocean currents, geostrophic circulation, and oceanographic effect. As pivotal factors, the inherent properties of microplastics (such as density, size, and shape) can also affect transportation and distribution modes (Fig. 3). During long-distance transportation via wind and turbulence, microplastics may serve as substrates for microflora in the ill-nourished open seas (Miao et al. 2019; Zettler et al. 2013). The microplastic surfaces are considered as novel habitats for microbial communities and termed as “plastispheres” (Zettler et al. 2013). Microbial life may facilitate the degradation of plastic waste (Yang et al. 2014) and

affect plastic debris density, buoyancy forces, and the sinking rate (Rummel et al. 2017). They may also influence the toxicity of microplastics (Imran et al. 2019).

Microplastics are small in size and may be mistakenly ingested by marine organisms, potentially resulting in physical or toxicological effects (Waller et al. 2017), and have a serial negative effect on the organisms throughout the food web (Lusher et al. 2013). Some studies have reported the existence of indigestible microplastics in deep-sea organisms in Western Pacific Ocean (Zhang et al. 2020) as well as in tiny shrimp living in the six deepest ocean trenches in the world (Peng et al. 2018). This suggests that the pollution by microplastics has already touched the deepest part of the world’s ocean.

Categories of Microplastics

Microplastics in the marine environment are composed of particles that are different in polymer type, size, shape, and specific density. They are widely divided into two categories: primary microplastics and secondary microplastics.

Microplastics, Fig. 3

Primary Microplastics

Primary microplastics are plastics produced for specific domestic or industrial applications with microscopic dimensions, including personal care consumer products (Fig. 4) and industrial or pharmaceutical products.

As for domestic utilization, microplastics are typically used in toothpaste, resin pellets, facial cleansers, and cosmetics like eye shadow (Zitko and Hanlon 1991). They were also applied to medicine as vectors for drugs (Patel et al. 2009). Virgin plastic production pellets, usually with diameter about 2–5 mm, can also be considered as primary microplastics, although their inclusion within this category has been criticized (Andrady 2011; Cole et al. 2011). Since microplastics have been approved for use in cosmetics in the 1980s, the use of exfoliating hand cleansers and facial scrubs containing microplastics has risen remarkably, and microplastic scrubbers have replaced customarily used natural ingredients (i.e., ground almonds, oatmeal, and pumice) (Derraik 2002; Fendall and Sewell 2009). The majority of facial cleansers now

contain polyethylene microplastics which are not captured by wastewater plants and will enter the oceans.

With regard to industrial applications of microplastic, the use of primary microplastics in consumer products constitutes millions of small sources, and the commercial or industrial use of similar products can be expected to constitute significant point sources of microplastics. From the microplastics-related reports, very few commercial-use products with primary microplastics are documented: abrasive blasting media for cleaning metal surfaces, abrasive hand cleaner soaps (Gregory 1996), and brief mentions of some unspecified use in petroleum industry.

Secondary Microplastics

Secondary microplastics, as the name suggests, are tiny particles of plastic derived from the breakdown of large pieces of plastics. The combined action of physical, chemical, and biological processes can weaken the structural completeness of plastic debris, leading to fragmentation

Microplastics, Fig. 4 The personal care consumer products containing microplastics

(Cole et al. 2011). Both the environmental factors (such as temperature, pH, salinity, and sunlight) and the properties of the microplastic (such as size, shape, and specific gravity) will act on the disintegration of large plastics. Macroplastics exposed to sunlight may suffer from light degradation, and ultraviolet (UV) radiation from the sunlight causes oxidation of the polymer matrix, resulting in bond cleavage (Andrady 2011; Moore 2008). Plastic debris on beaches is exposed to both high oxygen and sunlight, which will lead to rapid degradation. When the plastics losing the structural integrity were washed out to estuary and sea, they are cumulatively susceptible to fragmentation resulting from mechanical disruption (i.e., wave action, turbulence, and abrasion) (Barnes et al. 2009). In addition, the microbial activities and animal activities will also affect the fragmentation of macroplastics to microparticles.

Sources of Microplastics

The ocean-based sources of marine microplastics, resulting from commercial fishing, vessels, and other activities in marine environment, only contribute 20% of total plastic debris in marine environment (Andrady 2011). The discarded fishing net floating at sea may lead to

the continued trapping and killing of marine life, which is called “ghost fishing.” Products (such as clam netting, oyster bags, cages, and floats) applied in shellfish aquaculture can become marine debris when they are discarded or washed out during storms.

The microplastics from land sources contribute the remaining 80%. Land sources contain different origins that mainly are personal care products, air-blasting process, incorrectly disposed plastics, or leachates from landfill (Cole et al. 2011). A mass of marine microplastics are derived from land-based sources, such as floating garbage cans, litter tossed along roadsides, cigarette butts, food, agricultural plastic mulch, domestic sewage, beverage containers, and plastic straws; improper disposal; or illegal dumping. Once land microplastics are released into the natural water systems, most of them would be eventually transported to oceans by rivers, while the remaining would reside in freshwater environment, even including such isolated water systems as remote mountain lakes (Free et al. 2014). Light items, such as styrofoam, plastic grocery bags, and helium-filled balloons, can blow for miles in the air before landing in waterways.

At the land-water boundary, degenerating coastline structures (i.e., wharves, old piers, and bulkheads) will breakdown and finally become marine debris.

Sample Extraction

The small size (<5 mm) of microplastics makes it impossible to use direct visual selection methods for extraction. Concentrated collection methods or large sample collection methods are usually used to increase the possibility of microplastic detection, and it also makes it more difficult to separate and identify microplastics from collected samples, especially in sediments and organisms. Therefore, sample pretreatment and the method selection are essential for effectively extracting microplastics. The microplastic extracting process includes direct visual inspection, filtration, screening, and density flotation.

Separation of Microplastics from Sediments

Density flotation is commonly used to separate microplastics from sediments. It utilizes the density difference between the target components and impurities in the sample to achieve their separation and to float microplastics to the upper layer by using some intermediate media. The usual method is to add saturated salt solution to the sample to be extracted. The commonly used salt solutions include saturated NaCl solution, saturated NaI solution, saturated KI solution, saturated CaCl_2 solution, or saturated ZnCl_2 solution. Which salt solution to be used depends on the specific conditions of the experiment. Generally, the saturated salt solution is added to the sediment, stirred, and oscillated until it is fully mixed. The sediment-water mixture is allowed to be settled for 24 h until the stratification is obvious. The upper solution is transferred, and the microplastics are separated to the filter membrane by vacuum filtration. Due to the complex operation of artificial density flotation, if the number of samples is large, the experimental amount is large, time-consuming, and labor-intensive, and the loss rate is high. Therefore, researchers have designed a microplastic density flotation device for separating microplastics in sediments, which mainly relies on the principle of air flotation and continuous repetition to design, improve, or optimize the separation device to promote the performance of the device for extracting microplastics.

Separation of Microplastics from Organisms

The processing of marine organism samples is as follows: Collect samples, measure their size (using ruler) and weight (using electronic scale) after determining the species of samples, and then store them at $-80\text{ }^{\circ}\text{C}$. The samples are taken out and thawed before the analysis. In most cases, it takes nearly 12 h to thaw. After thawing, samples are rinsed with pure water for several times. Dissect the samples to obtain the desired biological tissue samples.

The key to separate microplastics from biological samples is to digest organic matter effectively without affecting the subsequent qualitative and quantitative analysis of microplastics. The biological sample treatment methods reported include acid digestion, alkaline digestion, and enzyme digestion. Acid digestion refers to the digestion of a sample with an acid solution. The commonly used acid solutions include HCl, HNO_3 , HClO_4 , and mixed acids (HNO_3 and HClO_4). Although the acid solution has a higher efficiency in digesting bioorganic matters, it will also digest some of the microplastics, resulting in microplastics, especially fibers, being underestimated. Similarly, alkaline digestion is the use of alkaline solutions to digest biological samples. The alkaline solutions NaOH and KOH were usually used, and the most commonly used mixed alkaline solution is NaOH and H_2O_2 . According to experimental data, the digestion rate of 1 mol/L NaOH on aquatic plankton can reach 90% at room temperature. The 10% KOH solution has high digestion efficiency and good digestion effect, and will not affect the microplastics recovered. Commonly used enzyme digestion types are trypsin and protease K. Because of the specificity of enzymes, enzyme digestion requires different types of enzymes for different biological tissues, so the requirements for enzymes are relatively high. In addition, the cost of enzyme experiments is also high, so few researchers use enzyme digestion methods. After digestion, saturated salt solution is also added for flotation treatment, and then the supernatant is transferred to the filter membrane.

Until now, there is not a uniform standard for the sampling and sample preparation for the microplastic analysis, which varies considerably

among researchers and would result in the variations of microplastic abundance for the same sampling location (Cai et al. 2018). Therefore, the standardization of sampling and microplastic extraction method is of vital importance for the comparison of microplastic abundance among different places.

Microplastic Identification and Quantification

Since the microplastics isolated from environmental samples are still a mixture of multiple substances, and the fragments of these mixtures have different characteristics in shape, size, color, density, chemical composition, etc., it increases the difficulty of microplastic separation and identification. Only by developing a specific methodological standard can comparable monitoring data be obtained and used to make reasonable assumptions about the distribution, quantity, and composition of microplastics. In the process of the study, the physical characteristics of microplastics are measured mainly by the visual method (i.e., the naked eye) combined with stereomicroscope to determine the shape, size, and color of microplastics. After visual selection, different instruments are used for detection. Due to the limitations of their own principles and characteristics, these instrument detection methods have certain advantages and disadvantages (Table 2).

The physical characteristics of microplastics mainly include its color, size, shape, and density. These characteristics will largely affect the migration and bioavailability of microplastics in the environment and will also determine the ecotoxicological effects of microplastics on marine organisms. According to researches, the shapes of microplastics mainly include fiber, pellet, particle, fragment, thin film, foam, etc., among which fiber is the most commonly detected shape. In most research reports, microplastics with a size less than 1 mm account for the largest proportion. The chemical characteristic index of microplastics mainly refers to the chemical composition of microplastics. At present, most of the research carried out generally uses Fourier transform

infrared spectroscopy (FTIR) and Raman spectroscopy (RS) to detect the polymer types of microplastics according to the comparison of their spectral results with the spectra library. Usually, only a polymer result with a matching degree greater than 70% can be considered as microplastics and recording its chemical composition. Using FTIR to identify, not only can we know the polymer composition, but also we can obtain information on the quantity of microplastics. Using this information, it is possible to speculate on the source, origin, and discharge path of the microplastics to a certain extent. The composition ratio of oxygen-containing bonds (such as hydroxyl, carbonyl, and other groups) in the infrared spectrum can also provide information about the weathering degree of microplastics. However, most of the microplastics in environmental samples have been weathered, and their composition is complex. They often need to be combined with multiple instruments to obtain a clear and accurate spectrum.

The Hazards of Microplastics

Microplastics can pose hazardous effects to the living organisms and environment due its chemical and physical properties, i.e., they are biochemically inert polymers, contain chemical additives, and could serve as vectors of pollutants and pathogens. The harmful effects of microplastics mainly include but not limited to the following:

Harmful Effects to Marine Organisms

Due to the small size of the microplastics in the ocean, it could be easily mistaken by aquatic animals and difficult to be eliminated from the body and eventually transferred to higher trophic organisms along the food chain. What's worse, microplastics of smaller size could easily enter the tissues and cells of vertebrates and accumulate in the body. Thus, microplastics in the body of living organisms could not only cause digestive system problems (intestine clogging, friction, penetration into the intestine wall, etc.) but also give rise to the problems of growth inhibition (reduction in feeding activity, malnutrition,

Microplastics, Table 2 Microplastic testing methods and analysis comparison

Detection method	Brief introduction	Sample preparation	Merit and demerit
Raman spectroscopy (RS)	Laser activation causes molecules to vibrate to measure molecular structure	Clean the sample	Advantages: no direct contact, no damage to the sample Disadvantages: The color of the sample will cause great interference to the detection, and sometimes the pigment map is obtained
Fourier transform infrared spectroscopy (FTIR)	Detect the vibration absorption of functional groups and chemical bonds, and compare with the library to get the polymer type	Clean the sample	Advantages: The interference of water vapor and carbon dioxide can be eliminated; the micro area can be scanned; the position of the sample can be visually seen and adjusted through the computer software; the sample is not damaged Disadvantages: If you want to obtain a higher degree of matching, the requirements on the sample are higher
Pyrolysis gas-liquid chromatography (Py-GC/LC)	The microplastics were decomposed by heat, and then the products were detected to infer the composition of the microplastics	The sampler shall be installed with a thermal desorption system	Advantage: It can analyze organic plastic additives as well as microplastic polymer types Disadvantages: damaged samples, complex equipment
Scanning electron microscope (SEM)	The surface morphology of the microplastic sample is obtained by electron beam interaction with the sample	Special coating protection, such as gold spraying, is required for samples under high vacuum conditions	Advantages: can get high-pixel images Disadvantages: Special coating is required; the cost is higher; damage to the sample
Environmental scanning electron microscope (ESEM)	The radiant energy of the microplastic surface is diffracted and reflected	/	Advantages: Obtain the image of the element composition and surface structure of the sample

M

starvation, etc.), enzymatic disruption, as well as the reproduction problems.

Harmful Effects to Human

The existence of microplastics in aquatic organisms, drinking water, table salt, sugar, and honey may become the sources of microplastics to human through their diets. Microplastics are able to pass through cell membrane and travel from gut cavity to circulatory system and subsequently induce digestive system problems, liver lipid disorder, inflammation effect, respiration problem, and even potential of cancer (De-la-Torre 2020; Yu et al. 2020).

Key Applications

Efforts for Controlling Microplastic Pollution

At present, the pollution problem of marine microplastics has become increasingly serious, and it has developed into a global pollution incident. Due to their enduring property, the effective treatment of microplastic pollution is lacking. The good news is the proposition and implementation of a “prevention first” strategy in lots of countries, starting from the management level to eliminate more pollution. Many countries have issued various plastic restrictions, for example, Chile has imposed a comprehensive plastic ban.

For reducing the use of plastic products, the Ministry of Environment of South Korea banned the use of disposable plastic cups in coffee shops from August 1, 2018. In the next year, the scope of “plastic limit” has expanded from coffee shops to supermarkets and roasting shops. Also, the “Law on Saving Resources and Promoting Resource Recycling” came into full force in South Korea in the same year. It stipulates that 2000 large supermarkets and 11,000 supermarkets with an area of more than 165 square meters completely stopped using the disposable plastic bags. In January 2020, the National Development and Reform Commission of China and the Ministry of Ecology and Environment issued the “Opinions on Further Strengthening the Treatment of Plastic Pollution,” which clearly sets the implementation goals into three stages in 2020, 2022, and 2025 to greatly reduce the use of plastic products. Plastic ban has been a global consensus and policy trend for environmental protection. In May 2019, the “EU version of the ban on plastics” came into full force, stipulating that the use of disposable plastic products, such as plastic straws, disposable tableware, and cotton swabs, will be prohibited by 2021. Moreover, the EU member states need to achieve the goal of recycling 90% of beverage bottles by 2029. The EU has also announced a ban on single-use cutlery, cotton buds, straws, and stirrers from 2021, as well as a reduction of other plastic items that are not included in the ban by at least 25% by 2025 in each member state. The “EU Plastics Act” also requires companies to take extended producer responsibility and economic responsibility for waste management and pollution control of disposable plastic products.

Introduction

The seabed ore processing contains ore dressing and metallurgy.

The ore dressing is based on the physical properties of different minerals in the seabed ore and adopts the methods such as gravity separation, flotation, and magnetic separation to separate the useful minerals containing manganese, nickel, cobalt, and copper from the gangue minerals. Metallurgy is the extraction process of different valuable metals from seabed minerals by the chemical methods such as roasting, smelting, leaching, solvent extraction, and electrodeposition.

The seabed metal deposits which are discovered so far contain polymetallic nodules, cobalt-rich crusts, and polymetallic sulfides. The polymetallic nodules and cobalt-rich crusts are belonged to polymetallic oxide ore; their main mineral phases are iron-manganese oxide, and the valuable elements are nickel, cobalt, copper, and so on. In the polymetallic nodules and cobalt-rich crusts, there are no independent minerals of nickel, cobalt, and copper; most of them replace the elements Mn and Fe in iron-manganese oxides in the form of isomorphism and are distributed in different iron-manganese oxide phases. Part of them are adsorbed on the surface of iron-manganese oxide phase or form the colloidal precipitates with iron-manganese oxide phase. The elements nickel, cobalt, copper, and manganese cannot

be separated by cheap physical ore dressing methods, and they are always recovered by the direct metallurgy processes or by the combination process of ore dressing and metallurgy that could separate part of entrainment bedrock by ore dressing before metallurgy process. The metallurgical process for polymetallic sulfides is similar with that of the sulfide ore on land, namely, first, the concentrate of sulfide is obtained by ore dressing and then go into metallurgy process.

In addition, seabed minerals can be directly used or prepared for functional materials such as catalysis, adsorption, and energy storage.

Mineral Process

Overview

Because the cobalt-rich crusts are always attached on the surface of bedrock, it is an inevitable problem that the bedrock is mingled into cobalt-rich crust ore in mining process, which causes ore grade dilution. Before metallurgy process, the pretreatment by ore dressing is necessary to remove bedrock, which could improve the elements' grade such as nickel, cobalt, copper, and manganese, at the same time decrease the metallurgy economic cost. The common ore dressing methods contain gravity separation, magnetic separation, and flotation. Therein, flotation separation outcome is the best, and its removing rate of bedrock and recovery rate of metals are higher than that in gravity separation and magnetic separation. Comparatively speaking, gravity separation and magnetic separation are more suitable for removing bedrock offshore, while flotation is more suitable for cleaner flotation onshore.

Gravity Separation

Gravity separation is based on the difference in density, particle size, and the rate and direction of movement between the gangue mineral particles and the useful mineral particles containing manganese, nickel, cobalt, and copper in cobalt-rich crusts to carry out separation each other.

According to the density difference between cobalt-rich crusts and bedrock, a part of bedrock could be removed by gravity separation. If the raw ore of cobalt-rich crust contains Co 0.44%, Mn 16.24%, Cu 0.086%, Ni 0.38%, and CaO 11.81%, when the ore size is less than 1.0 mm, the concentrate obtained contains Co 0.47%, Mn 17.14%, Cu 0.089%, and Ni 0.40%, and their recovery rates are about 95%, 94%, 92%, and 94%, respectively. The removing rate of bedrock is more than 90%.

Magnetic Separation

Magnetic separation is based on the difference in magnetic permeability between gangue minerals and the useful mineral particles containing manganese, nickel, cobalt, and copper to carry out separation each other. In the same magnetic field, the iron-manganese oxide minerals containing nickel, cobalt, and copper with high magnetic permeability are sucked up by the disk as concentrates, but the gangue minerals with low magnetic permeability are not sucked up and remain in the raw material as tailings.

According to the magnetic difference between cobalt-rich crusts and bedrock, a part of bedrock could be removed by magnetic separation. If the raw ore of cobalt-rich crust contains Co 0.44%, Mn 16.24%, Cu 0.086%, Ni 0.38%, and CaO 11.81%, when the ore size is less than 1.25 mm and the magnetic intensity is 1592.3 kA/m, the recovery rates of cobalt, manganese, copper, and nickel are about 96%, 96%, 91%, and 96%, respectively, and the removing rate of bedrock is more than 95%.

Flotation

Flotation is based on the difference in the surface physicochemical properties between gangue minerals and the useful mineral particles containing manganese, nickel, cobalt, and copper to carry out separation each other. Under the alone or combination action of collector agent, foaming agent, regulating agent, and dispersing agent, the air is blasted into slurry and by means of bubble buoyancy; the useful minerals are separated from gangue.

If the raw ore of cobalt-rich crust contains Co 0.44%, Mn 16.24%, Cu 0.086%, Ni 0.38%, and CaO 11.81%, the closed flow flotation test was carried out at the optimal conditions: feed size -0.074 mm of 70%, regulating agent TH 2000 g/t, and collector agent BK485 7000 g/t; the concentrate contains Co 0.56%, Mn 20.41%, Cu 0.10%, and Ni 0.46%. The recovery rates of cobalt, manganese, copper, and nickel are about 94%, 94%, 83%, and 90%, respectively. For the sulfide ore containing more than Cu 0.8%, Pb 2.5%, and Zn 2.5%, the metal recovery rate for separated sulfide concentrate (copper concentrate, lead concentrate, zinc concentrate) is more than 87%, and the metal recovery rate for the mixed sulfide concentrate is more than 92%.

chemical reaction; at high temperature conditions, a series of physical and chemical changes occur in seabed minerals, and the valuable metals are separated from gangue or other impurities. The hydrometallurgy is the process that seabed minerals contact with a solution (acid, alkali, salt, etc.); the useful metals in the minerals are transferred into liquid phase by chemical reaction and then separated or enriched.

The main processes that are studied currently are shown in Fig. 1. Typical processes contain APAL process, Cuprion process, HPAL process, reducing calcining-ammonia leaching process, chlorination calcining-leaching process, sulfating calcining-leaching process, and smelting-leaching process.

Metallurgy Process for Iron-Manganese Polymetallic Oxide Ore

Overview

The metallurgy processes of iron-manganese polymetallic oxide ore are divided into two major types: pyrometallurgy and hydrometallurgy.

The pyrometallurgy is based on the heat utilization generated by fuel combustion heat or electrical energy heat or the heat released by a

APAL Process

In APAL process, by adding reducing agent in leaching process, the structure of iron-manganese minerals is destroyed, so the elements nickel, cobalt, and copper distributed in iron-manganese minerals are exposed to acid solution and then are leached. The common reducing agents contain metal sulfides (such as pyrite, hydrogen sulfide, copper matte, etc.), sulfurous acid and sulfite (such as H_2SO_3 , SO_2 , Na_2SO_3 , $(\text{NH}_4)_2\text{SO}_3$, etc.),

Mineral Processing and Metallurgy, Fig. 1 Main metallurgy processes for iron-manganese polymetallic oxide ore

H₂O₂, salts containing Fe²⁺, organic reducing agents, etc.

By controlling the potential and pH of leaching system, in theory, nickel, cobalt, and copper can be leached selectively, while the whole manganese and iron go in residue. Actually, due to the special structure of iron-manganese polymetallic ore, it is difficult to control all manganese in residue (Tan et al. 2004).

When gas SO₂ is taken as reducing agent, the main chemical reactions during leaching are as follows:

For the leachate, first, copper is recovered selectively by solvent extract with Lix84; the organic phase loaded copper is stripped with electrolytic waste liquid and then goes into electrodeposition operation; the cathode copper is obtained; for the raffinate of copper, after purification, the valuable element separation process is as follows: precipitation of Ni and Co with sulfide, sulfuric acid leaching of nickel-cobalt mixed sulfide at high pressure, solution purification, separation of nickel and cobalt with Cyanex272, and electrodeposition; finally the metallic nickel and cobalt are obtained. The solution from the operation unit of precipitation of Ni and Co with sulfide mainly contains manganese sulfate. By precipitation with ammonium bicarbonate and concentration crystallization, the products manganese carbonate and ammonium sulfate are obtained. The process diagram of sulfuric acid leaching at atmospheric pressure is shown in Fig. 2.

For the raw material cobalt-rich crusts, the metal recovery rates for the whole process are about Co 95%, Ni 96%, Cu 74%, Mn 98%, and Zn 82%. The consumption of SO₂ and H₂SO₄ are 0.26 kg/t ore and 0.19 kg/t ore, respectively. The final productions are metallic cobalt, cobalt oxide, cobalt oxalate, metallic nickel, metallic copper, and manganese carbonate (Yin et al. 1998) (Jiang et al. 1998).

Cuprion Process

For the Cuprion process, in the ammonium solution containing Cu⁺, the iron-manganese polymetallic ore is leached when the reducing agent CO is introduced. In leaching process, manganese enters the residue in the form of precipitation MnCO₃ that can be recovered as MnCO₃ concentrate by flotation or used directly as a metallurgical material for different manganese products. Nickel, cobalt, and copper are leached as ammonia complex. For the leachate, part of them return to the leaching operation unit for supplying copper and carrying out the self-catalytic; the others go into solvent extraction process for the separation of copper and nickel, and then by electrodeposition the cathode copper and cathode nickel are obtained. For the raffinate from solvent extraction, by precipitation with sulfide, the intermediate product cobalt sulfide is obtained, which is used as material for preparing of metallic cobalt (Agarwal et al. 1979). The main chemical reactions in leaching process are as follows:

Reduction-Oxidation Reaction

Overall Reaction

Leaching Reaction

For polymetallic nodules, the ammonium-ammonium sulfate system is used. At the conditions leaching temperature 45 °C and solution potential -400 mV to -450 mV, the leaching rates of nickel, copper, and cobalt are 98%, 97%,

Mineral Processing and Metallurgy,

Fig. 2 Process diagram of APAL

M

and 90%, respectively. The leachate contains copper ion 10–12 g/L, nickel ion 13–15 g/L, and cobalt ion 2–3 g/L. At the same time, molybdenum of 96% in ore is leached, which can be recovered comprehensively (Jiang et al. 2005) (Fig. 3).

HPAL Process

The HPAL of iron-manganese polymetallic ore is similar to that of laterite ore. In leaching process, most of copper, nickel, and cobalt are dissolved, while iron and manganese rarely are leached. By solvent extraction and electrodeposition, metallic copper, cobalt, and nickel are obtained from leachate. At the conditions temperature 200 °C, pressure 3.1 MPa, partial pressure of oxygen

1 MPa, pH 1.63, and leaching time 1 h, the leaching rates of main metals in polymetallic nodules are Ni 80%, Cu 90%, Co 30%, Mn 5%, and Fe 2%, respectively. By solvent extraction with Lix64N, stripping with acid, and electrodeposition, metallic copper, cobalt, and nickel are obtained from leachate (Fig. 4).

Reducing Calcining-Ammonia Leaching Process

At 400–650 °C with different reducing agents, first, the high-valent iron oxides and manganese oxides in iron-manganese polymetallic ores are reduced into low-valent oxides; at the same time, the metal oxides of nickel, cobalt, and copper in minerals are reduced into metallic state and

Mineral Processing and Metallurgy, Fig. 3 Cuprion process

dissociated from iron-manganese polymetallic ores, and then the calcination is leached with the ammonia-ammonium carbonate solution which contains NH_3 50–100 g/L and CO_2 30–60 g/L; the leaching rates of metals are about Cu 85%, Ni 75%, Co 50%, and Fe less than 1%, respectively. For the leachate, by solvent extraction and electrodeposition, the metallic copper, nickel, and cobalt are obtained (Han et al. 1974) (Fig. 5).

Chlorination Calcining-Leaching Process

The chlorides of nickel, copper, cobalt, manganese, and iron have the properties such as low melting point, high volatility, and high water solubility; in chlorination calcining-leaching process, first, the iron-manganese polymetallic ore reacts with chlorinating agents at high

temperature, which makes the metal elements in ores convert into chlorides, and then they are recovered by hydrometallurgical processes. According to the type of chlorination agent, chlorination calcining is divided into the chlorination with hydrogen chloride and the reducing chlorination with chlorine salt (Cardwell 1973).

For chlorination with hydrogen chloride, iron-manganese polymetallic ore reacts with hydrogen chloride gas at 500–600 °C, and the elements manganese, nickel, copper, and cobalt form soluble chlorides, and then with water spraying at 300–400 °C, the ferric chlorides hydrolyze and convert into iron oxide; finally the chlorination product is leached with water and hydrochloric acid; the leaching rates of metals are about Ni 98%, Cu 99%, Co 97%, and Mn 99%,

Mineral Processing and Metallurgy,

Fig. 4 Process diagram of HPAL

M

Mineral Processing and Metallurgy,

Fig. 5 Reducing calcining-ammonia leaching process

Mineral Processing and Metallurgy,

Fig. 6 Chlorination calcining-leaching process

respectively. In leaching operation, the iron oxide goes into leaching residue. The elements nickel, cobalt, and copper in leachate are separated by solvent extraction and electrodeposition; the products are metallic copper, nickel, and cobalt. For the raffinate containing manganese chloride from solvent extraction, by evaporation, crystallization, and molten salt electrolysis, the product metal manganese is obtained.

For reducing chlorination with chloride salts, the ferromanganese polymetallic ore, CaCl_2 , and coke are calcined at 900°C for 1 h. The metal chlorides are formed first and then reduced into metal by coke; after that by magnetic separation, the concentration containing nickel, cobalt, and copper is obtained from calcination. The metal recovery rates are Cu 46%–88%, Ni 23%–32%, Co 7%–22%, Mn 0–9%, and Fe 0–9% (Hoover et al. 1975) (Fig. 6).

Sulfating Calcining-Leaching Process

For sulfating calcining-leaching process, first, the ore is decomposed by sulfuric acid in calcining process, and the valuable elements such as manganese, nickel, cobalt, and copper are converted into independent salt sulfate and then separated further by hydrometallurgical process. When the iron-manganese polymetallic ore reacts with sulfuric acid or sulfur dioxide at 650°C , the

calcination contains the iron oxide and sulfate of nickel, copper, cobalt, and manganese. When the calcination is leached with water, the leaching rates of nickel, cobalt, copper, and manganese are 92%, 97%, 87%, and 99%, respectively. For the leachate, by replacement of copper with iron powder, precipitation of nickel and cobalt with sulfide, acid leaching of mixed Ni-Co sulfides at high pressure, and solvent extraction, the productions are obtained such as sponge copper, zinc sulfate, cobalt sulfate, and nickel sulfate (Meyer-Galow et al. 1973) (Fig. 7).

Smelting-Leaching Process

In smelting-leaching process, by controlling the smelting reaction temperature, amount of reducing agent or sulfite agent, the elements nickel, cobalt, and copper in iron-manganese polymetallic ore are reduced into the metallic state and then form the alloy or sulfide with iron and finally are separated by hydrometallurgy process. The manganese goes in the slag in smelting-leaching process that could be used as raw material for preparation of various manganese products.

Smelting-leaching process is divided into matte smelting-leaching process and reduction smelting-leaching process.

Mineral Processing and Metallurgy,

Fig. 7 Sulfating calcining-leaching process

1. Matte Smelting-Leaching Process

In matte smelting-leaching process, the iron-manganese polymetallic ore is pre-reduced at 1100 °C with coal or fuel oil and then reduced into nickel-copper-cobalt-iron alloy at 1400 °C in electric furnace. The alloy ratio is 6%–10% which contains more than 90% of nickel and 75% of copper in iron-manganese polymetallic ore. The alloy is blown into high-grade matte with sulfide at 1350 °C in the converter. For the high-grade matte, by sulfuric acid leaching at high temperature and pressure, purification, solvent extraction, and electrodeposition, the metals such as cobalt, nickel, and copper are obtained. About manganese of 97% in iron-manganese polymetallic ore go into slag in smelting process and could be used as material for ferromanganese alloys (Sridhar et al. 1976).

2. Reduction Smelting-Leaching Process

In reduction smelting-leaching process, first, the iron-manganese polymetallic ore is pre-reduced with coke at 1100 °C and then smelted at 1400 °C with flux silica; the alloy is obtained which contains Ni 17.7%, Co 1.8%, Cu 9.6%, and Fe 67%. In smelting process, the recovery rates of nickel, cobalt, copper, and

iron are 93%, 68%, 87%, and 44%, respectively. For the alloy, by crushing, leaching, purification, solvent extraction, and electrodeposition, the products metallic nickel, cobalt, and copper are obtained (Richard Tinsley 1976) (Fig. 8).

Direct Application

Direct application means that there is no mineral process and metallurgy process, but according to the iron-manganese polymetallic ore prospects such as layered structure, tunnel structure, much microscopic pores, high-grade transition elements, and active silicon, they are used or prepared directly for functional materials such as catalysis, adsorption, and energy storage.

Catalytic Active Material

The active elements Ni, Cu, and Co in iron-manganese polymetallic ore play a catalytic role. It has the catalytic function in the field of the hydromethanation of CO and CO₂; the oxidation of SO₂, CO, and some alkanes; and the decomposition of NO_x. In the preparation process of carbon nanotube by CVD, the iron-manganese

Mineral Processing and Metallurgy,

Fig. 8 Smelting-leaching process

polymetallic ore is used as a natural catalyst to generate a large number of helical carbon nanotubes (Cheng et al. 2002).

Adsorption Material

The iron-manganese polymetallic ore has a selective adsorption effect on the elements in wastewater. The adsorption order for different elements is $Pb > Cd > Cu > Hg > Zn > Co > Mn > Ni > As$. The lead adsorption rate in wastewater is 90%~99% at pH 1.4~2.0, and the saturated adsorption capacity of lead can reach 200 mg/g ore. At pH more than 2.0, the adsorption rate of lead, zinc, cadmium, cobalt, copper, nickel, and manganese in wastewater can reach more than 99%, and the saturated adsorption capacity of zinc, cadmium, cobalt, copper, nickel, and manganese are all more than 40 mg/g ore (Tan et al. 2003).

Power Material

As a battery material, the iron-manganese polymetallic ores have good load characteristics, high discharge capacity, and good cycle stability characteristics. When the lithium-ion battery cathode material is prepared with iron-manganese polymetallic ore, the insertion potential of lithium ions is 2.6~3 V, and the actual reversible capacity of electrode reaches 110 mAh/g ore. There is still 70 mAh/g ore after 250 time cycle of charge and discharge (Yu et al. 2001).

Definition

Aquaculture production is growing and contributing in increasing volumes to global demand for marine foods. It is natural that fish farmers wish to expand and diversify their operations. Globally, the suitable land, fresh or coastal water, for fish farming has become more limited. Thus, fish farmers in many countries are considering expanding aquaculture production into locations that are further from the coast and where the conditions are harsher for fish, structures, and personnel.

Currently, the conventional gravity net cage is widely used for aquaculture production. The

gravity net cage system normally consists of four components: the float collar system, the net cage system, the sinker system, and the mooring system. The float collar provides buoyancy and the sinker system provides weight, maintaining a stable shape of the whole cage system. The net cage can significantly deform when subjected to ocean waves and currents. In moving the fish farm to exposed/offshore areas, environmental loads from wave, current and wind increase rapidly. Increased current loads will cause excess deformation of the net cage and might cause injury to the fish. Larger waves may cause fish to escape and challenges for operation and daily duties. In order to overcome these constraints on conventional fish farm, it is necessary to develop an offshore fish farm, which can be sited in high-energy environments.

Moreover, there are many problems with traditional fish farming including: accumulation of waste and feces on the seabed, disease, and fish escapes. Moving fish farms from the sheltered coastal areas to exposed sites leads to more space, stronger currents, and deeper waters. These can help to solve a number of these problems. Stronger ocean currents are particularly effective to dilute and disperse the fish waste and reduce the build-up wastes below fish cages. Sea lice settlement on fish is less successful under stronger currents and the impact of sea lice is therefore reduced. Greater distance to the shore also minimizes interactions with wild fish and results in negative impacts such as compromised reproductive health.

Given the legal and environmental restraints present in the aquaculture industry today, sea farmers have to look for new, innovative ways to increase volumes. The future will most likely be diversified – changing from one way of producing fish as seen today, to an industry approaching sea farming with several solutions.

Global Development of Aquaculture

The aquaculture industry has large regional differences. Regional variations are important in both the amount of fish farming activity and in

the diversity of farmed species. Norway, Chile, and Canada are leaders in the world for farming salmon, whereas China is the largest producer of farmed fish by volume. Some of the recent developments of offshore fish farm are listed in Tables 1 and 2.

Norway is a hub for offshore farming innovation due to its high value of its salmon farming. The Norwegian government has desired to have a significant growth in aquaculture. In 2015, Norwegian Ministry of Fisheries and Coastal Affairs introduced a free development concession for up to 15 years to promote new technologies that can solve environmental challenges and area issues facing the aquaculture sector. The aim is to support larger and more specific technology-oriented projects including prototypes, industrial designs, equipment in installations, and full-scale trial production. By the closing date 17 November 2017, the scheme had attracted 104 applications. Many applications are seeking to explore locations in more open waters than those presently used for salmon farming. The first project was accepted in 2016 and, as of today (May 2021), 22 projects have been granted for concessions. Two of these projects are described in greater detail below.

China is the largest player in the aquaculture industry. It is developing offshore salmon farms on an unprecedented scale with projects in the Yellow Sea, while the country's growing domestic appetite for other fish species will continue to drive nontraditional aquaculture practices. In 2016, the Ministry of Agriculture announced a "National Construction Plan for Marine Ranch Demonstration Zone (2017–2025)," which will build 178 pilot farms and increase China's aquaculture production by 30% by 2025. China's provincial governments are increasingly partnering with both privately owned and state-owned companies to build offshore finfish aquaculture farms.

New Technology in the Modern Aquaculture

Fish Health and Welfare

Farm-raised fish are susceptible to illness and disease. The welfare of fish is affected when

they are held in captivity as opposed to their natural habitat. Fish welfare is related to physical conditions at the aquaculture, such as fish density, temperature, water quality, disease, etc. Welfare issues may also be linked to other health problems that include dysfunctions related to poor feed or side effects of vaccines.

Good fish health is a precondition for fish welfare. In 2016 alone, 53 million salmon died in their pens in Norwegian fish farms, mostly due to sea lice (Veterinærinstituttet 2017). Improvement of the health status and welfare situation is crucial for future expansion of aquaculture industry.

The aggregation of fish in cages increases the risk of infections and diseases. Aquaculture installations in open waters may help mitigate some risk factors. For example, greater distances between cages will reduce the risk of diseases spreading. However, fish farming under exposed conditions requires fish to cope with stronger waves and currents. Weather conditions should be monitored to ensure that they are within acceptable limits for the fish.

The stress from handling of fish for counting and delousing treatments of lice compromises fish welfare and increases mortality. Sound digital sea lice monitoring method, efficient delousing methods, and robust regulations will pave the way for fish farming under good welfare and sustainable conditions.

Going to Offshore

Within the fish farming community, a site-classification system is generally accepted. The site-classification system is based on wave energy of local wave climates, which is linked to distance from shore. In a report "Farming the deep blue" published at 2005 (Ryan 2004), four site classes were conceived: Class 1 sheltered inshore site, Class 2 Semi-Exposed inshore site, Class 3 Exposed offshore site and Class 4 Open ocean offshore site. Traditional surface-based aquacultures are mostly suitable for Class 1 and Class 2. Further development of aquaculture system suitable for Class 3 and Class 4 requires novel technology (Fig. 1).

Moving offshore aquaculture to more exposed water is an ongoing process, and the destination is to establish complete offshore installations in open rough waters. Farming in exposed areas requires new technical solutions

combined with operational concepts for maintaining security and ensuring production reliability. Knowledge and experience will be essential in the progression to full offshore aquaculture.

Modern Aquaculture Structures, Fig. 1 Four site classes (Ryan 2004)

Submersible (Semi-Submersible) System

A submersible cage is a cage that can be lowered below sea level for a certain period, usually during storms. Some types are always partly under surface, where maintenance and normal operation are carried out at surface.

There are many advantages by lowering the facilities and keeping the fish further below sea

level. Wave forces on facilities are much smaller when below the sea level and risk from boat traffic and floating objects is reduced.

A new design for submersible cages was emerged in 2004, such as 40,000 m³ Ocean Globe (Fig. 2) from Byks of Norway (Fish Farming International 2004), but few of them have been built and tested in field at full scale. AKVA

Modern Aquaculture Structures, Fig. 2 Ocean Globe designed by Byks of Norway. (Source: <https://www.byks.no/>)

Group and Egersund Net have developed a concept for submersible cages called “Atlantis Subsea Farming.” The submersible cage must be submerged in the sea as far as possible and as little as possible in surface so that salmon lice will not become a problem.

Salmon farmers in Norway are also looking to the knowledge transfer from Norway’s offshore oil and gas industry to develop semi-submersible fish farm, which can move operations further offshore where environmental conditions are best suited for the growth of fish stocks.

Semi-submersible structures are designed to have small water-plan area, which is less affected by wave loadings. Larger buoyant tanks (pontoons) below the ocean surface can be ballasted/de-ballasted to match payload and free-board needs, as well as raise platforms from a deep to shallow draft. Salmar’s Ocean Farm 1 has now been operating for several years and utilizes such a concept to enclose a pen environment within its vertical “columns.” There are also a couple of projects that are under development, for example, “Havfarm 1,” “Aqua Semi,” “Arctic fish farm,” and “Smart fish farm”.

Closed and Semi-Closed System

Closed-containment systems (CCS) and semi-closed containment system (S-CCS) tackle some of the challenges with offshore farming. Placing closed or semi-closed system will enable to prevent escapes and sea lice as physical barriers.

As the facilities are closed, the feed will not be picked up and transferred out of facility by currents. Hence, the feed conversion ratio is decreased. Closed facilities need to process the water moving in and out of the facility. Water will be pumped up from 20–30 m below the sea level, where sea lice are not able to live. Moreover, closed facilities enable collection of sludge further reducing sea farming’s environmental footprint.

Many players such as Lerøy, Stadion Laks, and Mowi have chosen to focus on completely closed system, and the most famous of these projects is the “Egg” of Mowi. An egg-shaped farm is used to avoid lice and escape of fish, at the same time waste is collected at the bottom of the “Egg.” Mowi has also developed another closed concept, “Marine Donut,” which is a closed facility shaped like a donut.

Several companies such as Midt-Norsk Havbruk, Måvasøl Fiskeoppdrett, Nova Sea, AkvaDesign, and Hydra Salmon Company focus on partially closed facilities.

Recirculating Aquaculture Systems (RAS)

The use of recirculating aquaculture systems (RAS) will play an important role in the future aquaculture industry. Anadromous fish like salmon and trout are typically raised in fresh water until they are mature enough to migrate to salt water, where they are farmed in sea cages. With RAS technology these fish might spend their entire life on land by alternating fresh and saltwater environments through controlling the water chemistry.

Currently, sea farmers are looking into producing post-smolt of up to 500–1000 g or some even larger in land-based farming in order to decrease mortality and increase the number of production cycle (Ernst & Young 2019). RAS system can help to produce post-smolt with a good condition for better survival in sea when transferred to the open sea cage.

RAS technology can reduce water consumption and use lower energy for heated water during winter and spring seasons. Recirculation systems use 100 times less water per kilo of fish than traditional land-based systems. In addition, the water quality can be monitored continuously, which lessens the risk of disease and the need for antibiotics.

Denmark is a leader in recirculation system aquaculture. Hallundbæk Dambrug is using RAS technology to produce rainbow trout with recirculating over 96% of water (<https://stateofgreen.com/en/partners/akva-group-denmark/solutions/fish-farm-hallundbaek-dambrug/>). The discharged water is filtered, and the sludge is used for biogas or fertilizer. The discarded water is treated for removal of nitrate.

The carbon footprint is predicted to increase as fish farms move offshore due to increased energy use for transportation of materials, feed, and cultured fish. Facilities with RAS technology can be placed closed to the end market, reducing the transportation costs and carbon footprint.

Digitalization

Digitalization has the potential to simplify offshore operations and aquaculture is focusing extensively on digitally based technologies and solutions.

In Norway, a hub for offshore farming innovation, Fishtalk (AKVA Group) and Mercatus (ScaleAQ) are the main registration and reporting tools for production data. The aim of digital solutions is to reduce mortality rates, increase efficiency of farm inputs such as feed and vaccines, prevent disease and lice infection, and optimize farm management.

Even more interactive tools based on cloud services are anticipated for the future operation of large-scale offshore farm, providing real-time structural monitoring, complex analyses, and early warning system based on real-time processing of measurements. Cloud services can help to easily access relevant data and exchange the knowledge output and response process.

Digitalization has been promoted in application to a free development concession from Norwegian Ministry of Fisheries and Coastal Affairs. Some examples of different projects focusing on digital solutions are: Salmar's Ocean Farm 1 and Cermaq's iFarm.

Ocean Farm 1 is the first in the world to combine marine engineering, marine cybernetics, and marine biology via a "big data" approach fusing all the available underwater sensors and in this way offer decision support systems for the operators controlling and monitoring the feeding of the salmon and the overall physical environment of the sea (Fig. 3).

iFarm is a technology focusing on farmed fish health and welfare and recognizing fish as individuals – it thus has the potential to revolutionize fish farming. This allows us to monitor factors including growth, sea lice, disease, lesions, and other aspects that affect the health and welfare of the individual fish (Fig. 4).

Automation

Automation will be a strong contributor to efficient fish farming in the future. Automation can minimize the requirement for people in high-risk operations and can enable remote control.

Modern Aquaculture Structures, Fig. 3 Kongsberg digital farm. (Source: <https://www.kongsberg.com>)

Modern Aquaculture Structures, Fig. 4 iFarm from Cermaq. (Source: <https://www.cermaq.com>)

Based on technology development, new innovations and individual business goals, it is likely that the intensification of technology used in aquaculture will further strengthen the safety of the employees.

One application is the shift from on-site to a more off-site feeding control regime, where the

employee is located on a nearby safe feed barge or onshore. The feeding is carried out using a central feeding system involving video cameras and computers. This approach reduces the potential for incidents, during harsher weather conditions.

The other application is autonomous Remote Operated Vehicle (ROV). The equipment is being

developed with the intention of carrying out net integrity (check for holes) and net cleaning. Development and implementation of future autonomous vehicles for carrying out various operational aspects at cage site, is likely to lower the requirement for physical constraint and thereby enhance the safety of the employees.

Salmar's Ocean Farm 1 is one example of operation focusing highly on applying advanced technology for farming purposes. Ocean farm1 is fully automated and equipped with an integrated high-tech sensor and measuring system. The entire facility can be run by a crew of 2–4 people only and heavier manual operations are avoided. Therefore, all farming operations can be managed either onboard or remotely, minimizing the use of service vessels and outside equipment, making the entire facility more environmentally friendly.

Pioneer Projects for Offshore Fish Farm

Offshore fish farms operate in the open ocean far from the coast. The offshore fish farm should be

robust enough to resist heavier environmental condition, especially during storm events. Off-shore fish farms in Norway have been designed with experiences from offshore oil rig technology.

Fully enclosed cage is normally used for off-shore fish farm, which can be tethered or moored to the seabed. The offshore fish farm can be either partly or fully submerged in the sea in order to reduce the loadings from waves. Several designs have been developed in the world today, which is either for commercial production or experimental pilot unit with a small scale. Some recent pioneer projects in commercial production in Norway and China are introduced in the following sections (Fig. 5).

Sea Station

InnovaSea has developed a semi-rigid submerged net pen, "Sea Station (Fig. 6)." The system has a double cone form and includes a single central steel tube vertical spar inside a circular tube rim. These two elements are joined by radiating frame lines and the netting is fitted around this framework.

Modern Aquaculture Structures, Fig. 5 Offshore Aquaculture Cages (O'Shea et al. 2019)

Modern Aquaculture Structures, Fig. 6 Sketch for concept of Sea Station (Ryan 2004)

The central spar is used to provide buoyancy. The steel rim is to maintain net's shape and has ballasting capacities. In harsh weather, the cage can be fully submerged by varying the buoyancy in the central spar. A small platform on top of the central spar allows for feeding, access, and monitoring.

The system is moored at the central spar, allowing either for single point or fixed configurations.

The standard production model of Sea Station has a volume of 3000 m³ and the volume could be increased to 6000 m³ for larger version. 20 Sea Stations have been installed at Open Blue Farm, which is 11–12 km (7 miles) off the North coast of Panama. Currently 2000–3000 mt of cobia (*Rachycentron canadum*) can be produced each year (Fig. 7).

Aquapod

Marine biologists at Ocean Farm Technologies (Now InnovaSea) have developed a spherical fish cage, “Aquapod,” (Fig. 8) which can be carried on the high seas. The system can be fixed on deep sites or drift according to currents.

The cages consist of a large number of triangular galvanized steel frames. Their assembly makes it possible to obtain spheres measuring 8–28 m in diameter (capacity of 115–11,000 m³). Each triangle consists of a frame containing a polyethylene net, made of 80% from recycled products, covered with a

geometallic coating (<https://en.how10.com/1529763-the-aquapod-an-amazing-concept-of-marine-farms-on-the-high-seas>). The cages can be used on the surface or at depth, both on the coast and offshore. The triangles weigh between 40 and 50 kg in the air, but their weight vanishes once in the water. These spheres can be immersed with ease, allowing them to escape the action of waves, for example, in case of storm, or to protect them from any risk of collision with floating devices such as ships.

The Aquapod is firstly being trialed in Hawaii in a research project called Velella. Now 34 Aquapods are currently deployed in Puerto Rico, Indonesia, Panama, Florida, and Hawaii. They are mainly anchored, using long cables, in deep water with water depth between 200 and 300 m. In the future, Aquapods could potentially be equipped with propellers and a GPS system, and used to transport fish to arrive at their destination with the fish ready to harvest (Fig. 9).

Ocean Farm 1 and Smart Fish Farm

The world's first offshore fish farm with a semi-submersible design is already operating off Frohavet in Norway since September 2017. Ocean Farm 1 (Fig. 10) is owned by Norwegian owner, SalMar and was built in the China Ship-building Industry Corporation (CSIC) in Qingdao, China.

Modern Aquaculture Structures, Fig. 7 InnovaSea's Sea Station at Open Blue Farm. (Source: <https://www.openblue.com>)

SalMar has developed the world's first offshore fish farm from 2012 to 2015. In 28 February 2016, the Norwegian Ministry of Fisheries and Coastal affairs awarded first development licenses for aquaculture purposes to Ocean Farm 1 (Ocean Farming 2019). SalMar has invested approximately NOK 1 billion to design and develop Ocean Farm 1.

Ocean Farm 1 is an anchor fixed structure (diameter 110 m, height 68 m, and volume 250,000 m³) floating steadily in the ocean at water depths of between 100 and 300 m. It has a cylindrical net cage including two closable fixed bulkheads and a sliding bulkhead rotatable about the central column. The facility can be divided into three separate compartments if needed, enabling various fish operations. A bottom that can be elevated is provided between the two closable fixed bulkheads.

The net is fixed to the structure and has an incredible strength in order to prevent fish from

escaping. In addition, there is an extra net in the surface zone to protect against drifting matters.

Ocean farm1 is fully automated and equipped with an integrated high-tech sensor and measuring system. The entire facility can be run by a crew of 2–4 people only and heavier manual operations are avoided. Therefore, all farming operations can be managed either onboard or remotely, minimizing the use of service vessels and outside equipment, making the entire facility more environmentally friendly. This means that the fish can stay inside the net from stocking to harvestable fish.

After the facility was successfully installed, the company initiated a pilot phase with around one million 270–280 g salmon smolt in the cage. After 15 months of production in the sea, the fish has shown very good growth and that the quality is smooth and good. Few salmon lice have been observed and it has not been necessary to carry out a single lice treatment (Ocean Farming 2019).

Modern Aquaculture Structures, Fig. 8 Aquapod from InnovaSea. (Source: <https://www.innovasea.com/>)

M

Modern Aquaculture Structures, Fig. 9 Aquapod fish farm. (Source: <https://atlasofthefuture.org/project/aquapod-fish-farm/>)

Modern Aquaculture Structures, Fig. 10 Ocean Farm 1. (Source: <https://salmar.no/>)

A second production cycle started in August 2019 and so far in the cycle good biological status has been observed, with good growth, low lice, and low mortality.

Salmar is eyeing farming in deeper, more exposed locations after the Norwegian Ministry of Fisheries and Coastal affairs awarded permission to “the Smart Fish Farm” concept Fig. 11.

The Smart Fish Farm will have twice the capacity of Ocean Farm 1 and the total aquaculture volume of the chambers is 510,000 m³ when the operating depth is 45 m. The Smart Fish Farm concept is based on a semi-submersible steel structure consisting of a wide center column and a surrounding framework mainly with circular cross-sections. The framework stretches supports netting panels that provide eight separate chambers. The Smart Fish Farm has an estimated price tag of NOK 1.5 billion.

Although the Smart Fish Farm looks similar to Ocean Farm 1, it differs significantly in some areas. It will withstand substantially more exposed areas and have twice the capacity. But the main difference is that the central closed column will be equipped for processing fish, control

and management of the unit, as well as an advanced system for transporting fish related to the eight surrounding production chambers.

Havfarm 1 & 2

The Havfarm concept was developed by Nordlaks along with veteran ship creators at NSK Design in 2015 and awarded 21 licenses for a stationary Havfarm (Havfarm 1) (Figs. 12 and 13) and a dynamic Havfarm (Havfarm 2) (Fig. 14).

Havfarm 1 is a moored, long, and slender ship-like fish farm, 385 m long and 60 m wide. The unit consists of a bow section to reduce the wave and current loads in the cage system, a central open frame construction that holds six pyramid-shaped net pens, and a stern section with superstructure. The construction weight is around 33,000 tonnes and can hold up to 2 million salmon.

The Havfarm 1 is moored through a turret in the bow, and a total of 11 mooring lines and 11 anchors weighing 22 tonnes each. The unit will weathervane around this, thus making it capable of absorbing the feces and eventual feed spill without negative effects on the environment. This has resolved some of the challenges in the

Modern Aquaculture Structures, Fig. 11 Smart fish farm. (Source: <https://mariculture.no/>)

M

Modern Aquaculture Structures, Fig. 12 3D model of Havfarm 1. (Source: <https://www.tu.no/artikler/det-forste-lakseskipet-har-12-ganger-sa-mye-stal-som-en-vanlig-bronnbat/450811>)

aquaculture industry, where environmental footprint in small geographical areas is often a consequence if the natural current does not transport any feed spill and feces away.

Havfarm 1 was built at CIMC Raffles Shipyard in China and has been anchored at the site at Ytre Hadseløya, Norway in July 2020. The smolt will be released in traditional facilities for growth up to

Modern Aquaculture Structures, Fig. 13 Havfarm 1 on site. (Source: <https://www.nordlaks.no/pressekt-havfarm>)

Modern Aquaculture Structures, Fig. 14 Concept of Havfarm 2. (Source: <http://www.nskshipdesign.com>)

1–1.5 kg before the fish is transferred to Havfarm 1. The first stock of fish is scheduled to be released into the farm in September 2020.

Havfarm 2 will not be permanently moored but will use a dynamic positioning (DP) system to maintain position. The dynamic positioning

system allows vessels to automatically change their position and heading using thrusters and propellers. The unit can move to a sheltered location in the event of a storm by its own propulsion.

Havfarm 2 is planned to operate in two different zones: an exposed zone, which can be divided into

several anchor points, and a safe zone. Havfarm 2 shall be located in an exposed location when the weather conditions allow and shall shelter in a location less exposed to waves in harsh weather by its own propulsion. This design allows the unit to operate in larger and more exposed areas.

Deep Blue 1

In 2018 China's first deep-sea fish farm, "Deep Blue 1," (Fig. 15) was successfully launched by Wuchang Shipbuilding Industry Group and towed to Cold Water Mass area in Yellow Sea, China.

Modern Aquaculture Structures, Fig. 15 Deep Blue 1 in dry dock. (Source: <http://www.wanzefeng.com>)

M

Modern Aquaculture Structures, Fig. 16 Deep Blue 1 with new retrofitted tower. (Source: <http://m.rzw.com.cn/particle/485837>)

Modern Aquaculture Structures, Fig. 17 Hai Xia 1 in dry dock. (Source: <http://www.sasac.gov.cn/n2588025/n2588129/c14167773/content.html>)

The unit has a perimeter of 180 m and height of 35 m. The volume is 50,000 m³ and can produce about 1500 tonnes fish per season. In 2019 the “Deep Blue 1” was retrofitted with a tower of 35-m height (<https://ilaks.no/den-kinesiske-havfarmen-deep-blue-no-1-tilbake-i-drift-dette-er-nytt/>). The central tower (spar) houses machinery spaces, feed storage, and provides accommodation for operators (Fig. 16).

Its position underwater can be adjusted between 4 and 50 m to secure the best temperature for the salmon. By submerging under water, the pen will be able to withstand typhoon.

Hai Xia 1

The Dutch company De Maas SMC, a firm operating in the offshore oil and gas industry, has partnered with the local government in Fujian province to develop central column semi-submersible deep-sea fish farm, “Hai Xia 1 (Fig. 17).”

“Hai Xia 1” is 139-m in diameter and 12-m high, which is composed of a central cylinder

structure and the outer frame structure. The unit has a floater, which is below the surface and fused to the central spar. Water can be pumped in and out to sink/rise the unit. The spar houses the control room for the unit (<https://www.undercurrentnews.com/2018/10/01/expert-qa-designing-building-offshore-aquaculture-pens/>).

“Hai Xia 1” was constructed in a shipyard in the port city Mawei, Fujian and successfully deployed at East China Sea.

[Change for reuse](#); [Conversion for reuse](#)

Definition

Some decommissioning vessels, offshore structures, or their components are in relative good conditions. After the condition assessment and a series of maintenance and transformation, such as adding some new facilities, deck reinforcement, changing the single-layer tank to double layer, the updated vessels or platforms can continue to work for other projects.

Scientific Fundamentals

Background and Introduction

Shipowners scrap their ships for various reasons, such as aging, technical obsolescence, low earnings, high scrap prices, and bad market expectations (Stopford 2009). Most shipowners base this decision primarily on the price offered by the ship

recycling yard to buy an end-of-life ship. The recycling yard offering the best price usually wins the contract (Jain et al. 2017). The recycling yards offering “green” recycling services generally quote lower prices than other yards due to the higher cost of dismantling a ship by following international ship recycling regulations and health, safety, and environmental (HSE) management systems, or the ship recycling regulations such as the Hong Kong Convention and EU Ship Recycling Regulation are considered innocuous to environment. According to an estimate by Abdullah et al. (2012), the annual global capacity of recycling was around 780,000 lightweight tonnes (LDT) in 2012. Such yards generally offer a lower price compared to other yards operating in the same region.

The ship recycling process recovers steel and other materials in good condition. These materials can be reused and sold to the steel industry. The recycling shipyards in South Asia have been using substandard and standardized methods. The substandard method is the most common and corresponds to the (beaching) modality utilized mainly in India, Bangladesh, and Pakistan. The standardized method uses the landing and dry docking methods in Turkey, China, Europe, and North America (Ocampo and Pereira 2019).

Various shipyards have experience in managing repair and conversion projects with different vessels in order to extend their life or have more functions. The modification work includes but does not limit to structural steel renewal and refitting, hull blasting and painting, large machine shop facility, tail shaft and propeller repairs, engine overhaul, turbo charger overhaul, electrical repairs, automation and control systems, tank cleaning and coating, aluminum hull repairs, yacht repairs and refurbishments, deck machinery overhauls, pipeline and valve overhauls/renewals, and so on. During the modification progress, some guidelines or rules proposed by the official societies, such as DNV (2013), ABS (2014), BV (2017), CCS (2016) etc., should be obeyed or referred.

Apart from vessels, some of the offshore platforms are approaching the end of their production life and will need a strategy for removal, reuse, and recycling in the following future. For each

existing, as well as new, platform, it will be necessary to document the removal and modification procedures in detail. The opportunity to reuse a platform would require a favorable circumstance for old removed, reinstalled, and refurbished structure to be considered in comparison to building an entire new and purpose-built facility (Ole Olsen 2001).

It is therefore important that available reusable platforms are advertised well in advance. The operators must be aware of the reuse option when planning for new field developments. Within some years, the operators may have several existing platforms to choose from, when assessing the best option for the actual new field development (FIB 2002).

Key Applications

Representative Modifications

Oil Tanker Modification for FPSO/FLNG

In recent offshore oil and gas markets, there are two major approaches to build FPSOs (Floating Production, Storage, and Offloading Facilities). One way is to construct a new facility, and the other way is to modify oil tankers. Comparing with the latter approach, building a complete new FPSO is more time-consuming and demands for relative large funds. Hence, more shipyards and shipowners would like to choose modifications, which will save almost 10-month construction periods as well as 20% of the total cost. In some regular sea states, the rental fee of a FPSO

converted by oil tanker is more than the sum of modification fee and rental fee of oil tanker. Hence, it attracts more and more shipowner to modify their aged oil tankers to FPSOs (Zhang 2017). Some converted FPSOs in China are shown in Fig. 1.

The base of FPSO modification project is to choose a suitable old oil tanker. First of all, based on the requirement, crude production, deck area, and transportation ability of shuttle tanker in operation offshore oil field, the main dimensions and tonnage of the target oil tanker are determined. Afterward, the next step is to seek the suitable oil tanker according to the information in every way. Based on a set of hull design parameters, different hull configurations are evaluated and the respective advantages and disadvantages assessed in order to identify the best candidates for conversion (Biasotto et al. 2005). Furthermore, based on investigations on the target vessels, the cost of the whole modification project could be predicted, taking all factors into consideration, including the age of vessel, status of vessel and its facilities, etc. During the project demonstration of the conversion, the key factor of the feasibility is the economic performance compared with the new building FPSO. Finally, a structural assessment is necessary to judge whether the oil tanker meets the requirement of the design life.

The tanker conversion activities include the following parts:

- Hull conversion
- Mooring structure conversion
- Risers

Modification for Reuse, Fig. 1 Converted FPSOs in China. (Source: CNOOC)

- Deck reinforcement
- Accommodation – living and safety
- Helideck and deck cranes
- Hull corrosion protection
- Tanker propulsion
- Tanker services (power and heat plant)

Reuse of Offshore Platform

After deciding to totally remove a platform from the seafloor, operators have several options (O'Connor 1998; Van Voorst 1999; Gibbs 2000).

- The platform can be taken to shore, where it is disassembled and the components either recycled, sold as scrap, or discarded in landfills or other depositories.
- The structure can be reconditioned and reused. As an example, in 1997 a platform was removed from the North Sea, taken to shore and cleaned, refurbished, and shortened by 10 m (33 ft) and installed in another North Sea location. A few small platforms have also been reused in the Gulf of Mexico (Schroeder and Love 2004).
- Platform structure can be towed to a site remote from the intact platform (in either shallow or deep water) and reefed. Remote, shallow-water reefing has occurred a number of times in the Gulf of Mexico, with the most extreme example towing structures of two Tenneco platforms over 1480 km (920 mile) from offshore Louisiana to a site 2.4 km (1.5 mile) off Dade County, FL (Wilson et al. 1987).

A platform could be either reused in situ or removed, reinstalled, and reused at its new location. The design purpose, to produce oil and gas, could be changed as well. Finding another oil field that will match all the platform properties and production capacity is perhaps impossible but also not necessary. Some modifications and refurbishment must be performed anyway. Successful reuse of offshore platforms is dependent on water depth, seabed conditions, and other environmental loads.

An advantage for reused structures could be a shorter timescale from planning to production start. Another advantage is the good durability of

offshore structures, when well designed and built. There are also a lot of other proposed uses for old platforms: bridge piers, coastal defense, wind farms, and artificial reefs in addition to some more exotic examples as prison, casino, and fish farms.

However, there are also several issues existing:

- Skirts and bottom slabs are designed for particular soil conditions. If the conditions at the new location are totally different, this may make relocation impractical.
- Estimated life remaining (particularly with regard to fatigue) must be equal or longer than the estimated production life for the new field. Assessment of structure life remaining is important in this process.
- Using the platform for new activities requires due consideration of personal safety, transportation issues, and maintenance of the platform.

There will always be a day for end use and decommissioning for a platform; thus, the dismantling process will always be applicable. However, it should be noted that steel jackets will have an imaginable thickness loss due to the corrosion after its lifetime service. It is a possible choice to evaluate and certain the high-value elements which will be used in the following projects, in order to judge whether it is fit and economic for reuse. On the other hand, concrete gravity-based structures are usually not removable, and they are commonly modified and reuse in its “former” operation area.

Reuse for Subsea Components

It is widely accepted that subsea structures, such as wellheads, production manifolds, etc., are designed as a reusable facility. It will not only reduce the development cost of the offshore oil fields but also be beneficial to protect the offshore environment and maritime safety. As one of the intricate machined hardware sized for the flow rates, well shut-in pressures, installation vessel interfaces, and intra-field connections, it is normally designed to a high specification with corrosion resistance (Gorman and Neilson 2012). For these deepwater subsea structures, they are

utilized for production in a short duration. Besides, they hardly experienced external corrosion, so they are pretty suitable for a second-round operation in another oil field.

However, it should be noted that there exist many issues or obstacles before to make the decision to reuse this facility in another place. On the one hand, the factors, including valve size, material class, and its remaining useful design life, should be carefully evaluated and examined. On the other hand, the designers should check the tree's flowloop configuration as well as the valve number. According to the working area water depth, the subsea trees could be categorized into four types, which are mudline, diver assist, diverless, and guidelineless. The different type has its individual features, such as thickness, metal loss protection, and structure complexity. Hereby, this is another factor to be considered during the modification. Moreover, the wellheads, foundations, control systems, and flowline connection techniques may also affect successful reuse (Kawase et al. 1997).

Reuse for Mooring and Riser System

For the moored offshore platforms, there are mainly two mooring types, one is permanent and the other is disconnectable. Taking FPSO as an example, this system usually contains turret, mooring cables, and risers. Based on the evaluation from different aspects, each part of them could be reused in other oil fields.

In general, both internal and external turret design standardizations further facilitate reuse in that plans for additional, or future, risers may be well thought out avoiding the complications due to structure or piping interference in a future modification. The turret system piping, manifold, swivels, and safety features must be evaluated for compatibility with the new field requirements following a thorough inspection to determine the existing condition (Kawase et al. 1997). Furthermore, if the modification is adopted, it is best to perform this progress in a shipyard, and in some particular cases, dry-docking may be needed due to the project plan.

The mooring cables can also be reused with the proper consideration of corrosion, wear,

fatigue, and handling, so can the anchor components. However, a careful inspection work on field life, strength, design temperature, and installation equipment should be adopted in order to check the feasibility to the new field requirements. Similarly, the risers are also able to hold the reusable feature, although they are custom-designed for their corresponding area. Specifically, the lazy wave and free hanging catenary risers are easier to re-utilize as the riser forms part of the flowline after touchdown. However, the inspection before the second-time adoption contains much more terms, such as service life and type, design temperatures and pressures, site particulars, riser configuration, and installation equipment. Recertification of the riser by the riser manufacturer or the certifying authority may also be required. Moreover, a detailed examination of the external sheath and the end fittings will be required. Buoyancy modules will need to be removed, refurbished, and replaced during reinstallation (Kawase et al. 1997).

Future Technics

Combined Offshore Energy Harvesters

Renewable energy resources, called sustainable or alternative energy, are energies generated from natural resources such as wind, sunlight, tide, hydro, biomass, and geothermal which are naturally replenished (Díaz-de-Baldasano et al. 2014). The main challenge of replacing legacy systems with more environmentally friendly alternatives is how to capture the maximum energy and deliver the energy at a minimum cost. A combination of two or more types of energy sources might provide a good chance of optimizing power generation system (Da and Khaligh 2009). Hence, a series of novel offshore structures for renewable energy power generations, such as wind/tidal, wind/wave, wind/solar, and so on, are developed. However, most of present offshore energy harvesters only have single function. In order to establish the hybrid power system, a modification is necessary.

CO₂ Emissions of Oil and Gas Production Platforms

Oil and gas platforms are energy-intensive systems, and each facility uses from a few to several hundred MW of energy, depending on the petroleum properties, export specifications, and field lifetime. For instance, the Norwegian oil and gas offshore sector has contributed for about 20–30% of the total Norwegian CO₂ emissions in the last decade, and this number is expected to stay in the same magnitude in the coming years. These emissions are caused in a large share by the combustion of natural gas in gas turbines to produce the power required to drive the compression and pumping operations, and the remaining is associated with gas flaring and diesel combustion. Several technologies for increasing the energy efficiency of these plants are investigated. Among them, it is an effective way to make some modifications or add some new facilities on the old platforms in order to lessen CO₂ emissions. They aim at reducing the electrical or thermal energy use, by redesigning some sections of the processing plant (production manifolds), re-dimensioning the compressors (gas recompression and treatment), promoting energy and process integration (heat exchanger network), and implementing expanders and waste heat recovery cycles. The savings potentials differ significantly from one platform to another (Nguyen et al. 2016).

Fish Farms

Nowadays, more and more researchers are considering setting up fish cage structures in large offshore structures such as platforms or jackets to create such new structures for offshore ranching. However, there still exist several issues to be taken into account. On the one hand, there will be many difficulties for the cage structure, such as motion response according to the change in draft, lowering and lifting, and so on. On the other hand, storm damage due to snagging and fretting of nets or cages is likely to be frequent and not easily repaired. Furthermore, the development and maintenance cost is likely to exceed the profits of inshore fish farming.

Modification for Entertainment, Tourism, or Living

Apart from the above solutions, there is an interesting and creative way to reuse the retired offshore platforms. This answer is to modify the platform as a sea-view hotel or a diving resort. The Seaventures (see Fig. 2) is a dive resort made from a converted oil rig offering a perfect location for nonstop diving. Besides, the dive resort also provides accommodation and entertainment facilities. Another similar idea is performed on the abandoned oil platform “Albuskjell 2/4-F” by Norwegian architect Sverre Max Stenersen. The platform is modified to add some living or business features, and it is planned to be located in the port of Trondheim.

Monopile Foundations in Offshore Wind Farm

Guoliang Dai
School of Civil Engineering, Southeast
University, Nanjing, China

Synonyms

[Single pile foundation](#)

Definition

Monopile foundations refer to the commonly used steel pipe piles with large diameter and thick wall, which are usually driven (hammered) into the seabed.

Scientific Fundamentals

Scope for Development of Monopile Foundation

The energy crisis and air pollution caused by traditional energy resources around the world have led to an urgent need for clean and renewable resources in the twenty-first century. Under this background, offshore wind farms have become an important source of renewable energy in recent years. The first large-scale offshore wind farm was successfully installed in 2002 in Denmark, which is the

milestone of offshore wind farm construction. Since then, in Europe, there have been booming developments in offshore wind farm benefitted from strong political and financial support. Moreover, political strategies in Europe, and in the United States, aim to enlarge to the offshore wind energy sector to limit the dependence on oil, gas, and coal (Malhotra 2011). When it comes to China, the first large-scale offshore wind farm (offshore wind farm of Donghai Bridge) is built in Shanghai by 2009, indicating the new epoch of offshore wind energy. By 2015, the capacity of offshore wind farms in China has reached over 1.01 GW, and several projects that made this happen are shown in Table 1. The relative statistical data of several countries of annual offshore wind capacity from 2012 to 2015 and 2017 are shown in Table 2 and Fig. 1, respectively.

There are several types of foundations to support offshore wind turbine structures, which include monopile foundations, gravity foundations, tripod foundations, suction foundations, and floating foundations. Each type of foundation has their own structural advantages and limitations. Among these foundations, monopiles are most commonly used foundations in offshore wind farm as they can withstand harsh loading condition transferred from the supported superstructures in deep waters with the advantage of lower cost, more structural simplicity, and smaller foundation settlement. In Europe, the monopiles constitute 81.7% of all installed turbine substructures, which are shown in Fig. 2. The same phenomenon can also be found in China's offshore wind farms.

Monopile Foundations

Monopile foundations are usually steel pipe piles with large diameters and thick walls that are driven (hammered) into the seabed. Carlo (Ortolani 2017) and Byrne (2015) reported commonly used monopile foundations with large diameter (D) of 4–7 m (Fig. 3), sometimes even up to 10 m in diameter with their lengths of 40–50 m (while in China, the length of several monopiles is as long as 70 m, i.e., monopiles in Xiangshui offshore wind farm). The

monopiles with large diameters and long embedment would allow the supporting of larger wind turbines – from 3–4 to 5–8 MW of power capacity and with the installation possible in deep waters of 30 m. “Offshore wind turbines with 6–8 MW capacity have already existed in the energy market, with superstructure where the height of the hub can reach up to 100 m and blade diameters up to 150 m, e.g., DONG's Westernmost Rough and Burbo Bank Extension wind farms” (Ortolani 2017).

Components of Monopile-Supported Offshore Wind Turbine

As illustrated by Velarde (2016), a typical monopile-supported offshore wind turbine consists of a steel pipe pile with a large diameter which is driven into the seabed by a steam or

hydraulic-powered hammer. The support structure consists of three main parts: foundation pile, transition piece (or without), and tower as shown in Fig. 4. These components of the support structure hold the rotor-nacelle assembly in place. The nacelle houses electronic and mechanical parts of the turbine such as gearbox and generator. The function of monopile is to transmit loads such as wind loads (on the turbine and tower), wave and current loads, lateral load, and overturning moments (due to cantilever structure of turbine) and axial loads (due to the weight of the superstructure) to the underlying soil without any failure over the design period. The monopile is connected to the tower by the transition piece which is grouted. This transition piece can be used for anchoring of boats, as a ladder, as platform, and can also be used for correction of vertical misalignments during pile driving. The

Monopile Foundations in Offshore Wind Farm,

Fig. 3 A 7.5-m diameter monopile in an offshore wind

monopile and transition piece assembly are the most important parts to connect the rotor-nacelle assembly to the tower.

Installation of Monopile Foundation

The installation procedure for monopile includes: (1) Transportation to site by feeder barge, (2) transportation to installation vessel or floating vessel, (3) upending and lifting into position, (4) alignment to position, and (5) driving or drilling into the seabed. The installation of monopiles can mainly be done in three methods (Fig. 5) depending on the subsurface conditions of the seabed: (1) Impact method, (2) vibratory method or grouted into sockets, and (3) drilled into rock. The drilling method is more efficient and less cost-effective of installation than the driving method. Most offshore piles are installed with impact-driven piles, which produce noise, and the noise must be reduced using expensive techniques to limit the damage on sea mammals. Vibratory driven piles are commonly used in sandy soils; the pile is driven at the head by

applying quick sequences of downward and upward motions to the pile in order to reach the required embedded length without noise mitigation system and fatigue induced by impact driving (Matlock 2015). Drilled method is used when the soil is too hard for installation. This installation method has large effect on the bearing capacity of piles. Monopiles used for offshore wind turbines can be considered as low-displacement piles as Pedram (2015).

There are many researches focusing on the effect of installation methods on the pile behavior; this has been studied by various methods such as field tests, laboratory study, mechanical modeling, or numerical studies. During design of monopiles, installation methods should be taken into consideration while determining soil strength and stiffness around pile body (Phanikanth et al. 2012). A typical installation physical modeling was proposed by Hokmabadi et al. (2015), a numerical modeling by McCabe and Sheil et al. (2015), and some field testing/observations was done by Zhuang and Cui ((2015); (Kog 2016; Eslami and

Monopile Foundations in Offshore Wind Farm,

Fig. 4 The monopile support structure

Fellenius 1997; Eslami et al. 2012). Zarrabi and Eslami (2016) has conducted more than 30 axial compressive and tensile load tests which were performed on various monopiles installed with six different installation methods (jacking, drilling and grouting, driving, drilling and placing, screwing, and postgrouting). From the results, Zarrabi and Eslami (2016) found that jacked and precast-in-place piles had the highest and lowest capacities, respectively. Also driven piles had the next highest capacity among other piles.

Field Tests Example on Monopile with Large Diameters

In offshore wind projects, field test on monopiles is an essential part in construction; the main purpose of the field test is to make sure of the bearing capacity before construction and to prove that the existing pile is secure under static or dynamic loading conditions.

Depending on the force direction, there are two kinds of loading methods: vertical loading tests under axial-compressive and tensile loads, and lateral load test. Depending on the test methods, the commonly used tests are conventional loading test, bidirectional test (Osterberg cell or O-Cell test), low strain impact integrity test, and high strain impact test.

The conventional axial compressive load test is one of the most commonly used methods to determine the vertical bearing capacity of monopile in offshore area. Anchor piles as a load test reaction system and a jack as a force-applied system are used to offer the vertical load on the pile head, which can be seen in Fig. 6; the conventional static load test is a reliable method to determine the bearing capacity of piles (Russo 2013). But for monopile with very large diameter, it is unattainable for this loading test to determine the capacity behavior of these piles (where the load test reaction systems often do not have the capacity to take the pile all the way to plunging).

Monopile Foundations in Offshore Wind Farm, Fig. 5 Pile installation by (a) impact method (Yushan Super Bridge project), (b) vibratory method) (De Neef et al. 2013), and (c) drilling method (Mai 2012)

Monopile Foundations in Offshore Wind Farm, Fig. 6 Conventional load test of an offshore wind project in China (offshore wind farm of Donghai Bridge)

As for the *bidirectional* test, it can solve the above problem, and this method has been successfully used in some offshore wind projects. In bidirectional load test, a very important equipment is load cell, which is shown in Fig. 7. During the loading process, the top and bottom planes of load cell were apart and pushed their corresponding pile sections to move contrarily until the ultimate resistance of top pile is reached. The displacement versus applied load of top and bottom planes was recorded at each loading step. However, there is a need for several hypotheses in bidirectional test to transform experimental results into those of an equivalent conventional load test.

As for the low-strain impact integrity test and high-strain test, the low-strain test can be

Monopile Foundations in Offshore Wind Farm, Fig. 7 (a) Bidirectional test of pipe pile and (b) Load cell of pipe pile

used to find out the integrity of pile body, while high-strain impact test can be used to determine the vertical bearing capacity of pile only if the result can be compared with that of static load test.

Sample Field Tests on Monopile

In this part, the field static loading tests results of an offshore wind farms in China are introduced. These loading test methods include axial-compressive and tensile load test, as well as lateral load test. The wind farm project is located at the

coast area of Jiangsu province; the soil profile here consists of marine clay and sand. The relative parameters of piles (A and B) are shown in Table 3, the corresponding vertical capacity test results are shown in Figs. 8 and 9, and the shaft resistance of each layer of piles A and B is shown in Table 4.

Monopile Foundations in Offshore Wind Farm, Table 3 Test pile parameters in field test (Li et al. 2019)

Project name:	Project 1	
Pile name	A	B
Pile length (m)	71.5	77.5
Pile diameter (m)	2.0	2.0
L/D	35.8	38.8
Test method	Axial compression & tensile load test, lateral load test	Axial compression & tensile load test

Monopile Foundations in Offshore Wind Farm, Fig. 8 (a & c) are downward load-displacement of pile top from test of pile A and B, respectively; (b & d) are

uplift load-displacement of pile top from test pile A and B, respectively. (Source: Li et al. 2019)

From Fig. 8a and b, the vertical compressing capacity of A is 32,800 kN, the total shaft resistance is 31,076 kN, and the uplifting capacity of B is 22,800 kN; in Fig. 8c and d, the vertical compressing capacity of A is 34,850 kN, the total shaft resistance is 33,260 kN, and the

uplifting capacity of B is 22,000 kN. From Fig. 9, the displacement of the pile at load-applied point of 500 kN is 0.0779 m. The ultimate shaft friction resistance at different soil layers is shown in Table 4. From these results, we can find that the friction resistance from compressive load test is much larger than that from tensile load test.

Monopile Foundations in Offshore Wind Farm, Fig. 9 Lateral load-displacement at mud line of A

The Problems with the Use of Monopiles

Monopiles are widely used in offshore wind projects, while large diameter single piles with diameters of 5–10 m (Byrne 2015) are considered for future design purpose in deep offshore areas. The most difficult problem in the use of monopile foundation is the current design methods, originally used for small diameter piles. There are many problems when using the traditional design method on the large diameter monopiles, some of which are mentioned below:

Monopile Foundations in Offshore Wind Farm, Table 4 Shaft resistance of A and B from load tests

Pile name	Soil type	Thickness of each layer (m)	Shaft resistance (kPa) from compression load	Shaft resistance (kPa) from tensile load

Definition

Moored ship means a ship to be secured or fixed to some bodies by using cables, lines, or anchors.

The ship is often used to assist underwater activities such as diving, seeking, and retrieval. It could also be used to perform oil and gas exploration or exploitation at seas.

Introduction

Interests in the Arctic and sub-Arctic waters have been growing since several large big hydrocarbon fields in the Barents and Kara Seas were discovered. However, it is still challenging to perform hydrocarbon exploration and exploitation in these locations, which always involves risks from low temperature, sea ice, wind, waves, currents, darkness, icing, etc. One of the biggest challenges in the Arctic and sub-Arctic areas is the sea ice. It exists in many features, such as level ice, broken ice, ice ridge, iceberg, and so on. Resulting ice loads are dominant to open water load, wind load, current load, and wave load on most occasions for polar ships as well as offshore structures. To resist ice action and keep the station, different marine structures are used for drilling, production, and offloading operations in ice-covered waters. Fixed structure is a good solution to shallow water operation, such as gravity-based structure, jacket platform, artificial island, etc. As water depth increases, moored floating vessels are shown to be attractive. This chapter will mainly focus on the types of Arctic moored ship, industrial operations,

numerical simulation, model tests, and full-scale measurements.

Moored Vessel Types

Generally speaking, there are three kinds of marine structures. The first is bottom-fixed. The second is moored with mooring lines. And the third is the dynamic-positioned. Mooring systems are often used for polar ship station keeping in severe ice with medium waters. As we know, ice crushing against vertical structure often leads to large ice force which may exceed capability of the mooring system. Thus, moored vessel is required to be designed with downward slope which could bend pack ice easily. Two typical concepts are included herein. One is traditional ship-shaped structure and the other one is the conical structure.

Ship-Shaped Structure

A ship-shaped structure includes relative long parallel mid-body and icebreaking bow. Some have also icebreaking capability with stern. In ice-covered waters, ice drift direction often changes from time to time. This makes ice vaning capability of moored ship very important. The moored ship (as shown in Fig. 1) should have a quick response to change heading under ice action and keep heading toward the ice drift. In general, a ship-shaped structure preforms well in surge, pitch, and heave but may experience large

M

Moored Ship in Ice,

Fig. 1 Moored ship ice in ice

sway and roll motion when ice intrudes from sideways.

Relevant experience with moored structures in ice is obtained from drilling operations in the Beaufort Sea. Starting in the mid-1970s to the late 1980s, Dome Petroleum deployed floating drillships named Canmar during the summer months. These were moored on site during the summer (open water) months, where relatively light ice conditions were encountered (Wright 1999). With the support of icebreakers, these drillships developed the capability of station keeping in a variety of ice conditions. This extended their open water operating season, although they did not work extensively in heavy ice. Unfortunately, although Canmar gained a great deal of experience with their Beaufort Sea drillships, there is very little documentation about their operations, particularly with regard to the load levels experienced by these moored vessels in ice.

For the development of the Grand Banks oil fields, the Terra Nova scheme was implemented (Wright 1998). It involves a floating ship-shape production vessel with integrated storage and offloading systems (FPSO), which is designed to continue operations in most environmental conditions. The FPSO could disconnect with the mooring lines and risers system and move off the site when avoiding severe ice actions. This approach is attractive for operations. The vessel has been operating year-around with light ice conditions encountered. The advantage is that capital cost is low and response to the ice conditions is quick, but the disadvantage is the potential for much downtime due to ice and the associated production delays. This experience has shown that moored vessels, with adequate levels of ice strengthening and ice management support, can be very effective in a wide range of moving pack ice conditions.

It is expected that the gas-condensate field Shtokmanovskoye, located in the central part of the Barents, will be developed in the near future. The water depth is 340 m. At this field, both occurrences of sea ice and icebergs have to be expected during operations. The general offshore facilities development scheme that has been

selected is based on the Subsea Production System (SPS) tied-back through a system of umbilical, flow line, and riser (UFR) to the ice-resistant ship-shaped Floating Production Unit (FPU) hosting gas processing, gas compression, living quarter, power generation, and all other utilities required to operate.

Some concept studies for different kinds of marine structures have been tried in model scale with level ice, broken ice, and ice ridge. Løset et al. (1998) performed a series of model-scale tests with the Submerged Turret Loading Concept (STL) for loading oil offshore in the Hamburg Ship Model Basin (HSVA) ice tank in Hamburg. The modelled ship had a conventional icebreaking bow at a scale of 1:36. The purpose of the tests was to study the feasibility of the STL concept in level ice, broken ice, and pressure ridges. It was found that pressure ridges produced for the model tests may cause forces over the capacity of the STL system. Later, a number of model tests with another concept were conducted in the HSVA ice tank (Løset et al. 2003). The concept comprises a single anchored moored ship located in the wake behind a moored buoy floating freely on the surface. The buoy with smooth surface was expected to break the ice in upward bending and also ridges. However, the results show that it is probably not practically feasible to apply a buoy with enough buoyancy to break the design ridges since ridges may exceed the breaking capacity of the buoy unless disconnection of the ship can be done. Ettema and Nixon (2005) reported model test data regarding ice-rubble loads acted on a moored conical platform. How ice-rubble loads were influenced by horizontal stiffness of the platform's mooring system were investigated with great interest. Aksnes (2009) used a simplified moored ship to perform model test in level ice. The ship model was fixed except surge degree of freedom with a linear spring. Different dynamic properties of the ship model as well as drifting ice were studied and analyzed.

Bonnemaire et al. (2008) proposed a new concept for offshore offloading operations in ice. The concept named Arctic Tandem Offloading Terminal (ATOT) is composed of a turret moored offloading icebreaker and an

offloading tanker in tandem. It was tested in the HSVA ice tank with focus on the measurement of mooring loads during interactions with ice ridges in head on drift.

Aker Solutions and Aker Arctic proposed an Arctic drillship concept which enables to extend operation season in waters with sea ice (Bruun et al. 2015). The concept was developed to perform drilling, coil tubing, wireline operations, and running and pulling x-mas tree through a forward turret for low air temperature.

The design work was performed regarding sizing of the hull, drilling, turret, and station keeping system. General arrangement drawings were developed for each deck level, and the technical work was well documented through development of an outline specification. The drillship was designed to operate in late ice season, summer season, and early ice season. The corresponding mooring system could resist a maximum load equivalent to interaction with level ice cover of 1.5 m thickness during ice drift change. This includes design of hull lines for effective ice breaking, a forward turret position to reduce the ice load during change of ice drift direction, and station keeping system (mooring system) with a high restoring capacity. A dual-class design complying with both RMRS (Russian Maritime Register of Shipping) ARC 6 and PC 5 (Polar Class) was performed. The thrusters can be used for both transit and station keeping. There are three open podded thrusters at stern and two nozzle retractable thrusters at bow used for both transit and station keeping. For drilling in open water, the five thrusters provide DP3 capability, while for drilling in ice, the turret mooring system will be used for station keeping assisted by aft thrusters during rotation in ice (forward thrusters will always be retracted when operating in ice).

Conical Structure

Considering the limited ice vaning capability of ship-shaped structure, conical structure with an axis symmetrical hull was developed. The waterline is circular. The structure does not need to change heading. Therefore, ice vaning is no longer required. The cost is that it may result in weak performance in surge, heave, and pitch.

A typical conical drilling unit, the Kulluk platform, was designed with a variety of special features to improve the performance under ice conditions in the shallow water (Wright 1999). It was deployed in water depths ranging from 20 m to 60 m. The system has a downward sloping circular hull near the waterline that breaks the oncoming ice mainly in flexure and an outward flare near the bottom that clears the broken ice cusps away from the moon pool and mooring lines. The strong mooring system could resist ice forces up to 450 t. It worked successfully with the downtime in operations less than 10%, but at a cost of extensive ice management by three icebreakers.

Considering the possible change in ice drift direction which may lead to a significant increase in ice load on the hull, some buoy-shaped structures based on prototype of the Kulluk were tested. The structure of this sort is attractive in that the need to keep heading toward the ice drift is no longer required. The conical structure FPU-Ice (by SEVAN Marine) was tested in the spring 2008 at HSVA (Løset and Aarsnes 2009). The purpose was to study the ice load level on the structure and its response in extreme first-year ice including the interaction with unmanaged ice ridges exceeding 20 m draft.

A Joint Industry Project was reported by Bruun et al. (2011) on development of conical floaters in ice, where a typical SPAR platform was developed during the project. Two large ice model test campaigns were performed in the period 2007–2010. The objectives were to investigate different floater geometries and ice model test setups (model fixed to a carriage and pushed through the ice vs. ice pushed toward a floating model moored to the basin bottom) and their influence on the ice failure mode and structure responses in the various tested ice conditions.

Main Considerations of Moored Ship Design

Three key elements should be well considered when designing a moored ship operating ice-covered waters. The hull lines of the vessel should

be optimized to reduce ice impact as much as possible and minimize the response of hull. The mooring and riser system are required to resist global ice action and keep natural position within an allowable watch circle. To estimate ice-moored ship interaction, some analytical methods and ice model tests are applied to calculate ice loads, mooring loads, and the responses of the ship, based on which both hull lines and mooring systems could be designed safely.

Vessel Systems

The specific hull lines of a moored vessel are important in that they have a strong influence on the vessel's ability of icebreaking and ice clearing process and the resultant ice loads that it is exposed to. In particular, the ice forces are significantly affected by the width of the vessel. The ice forces increase with beam size. The icebreaking load level at the waterline is often affected by the shape of bow to a large extent. How to optimize the bow shape to reduce ice load is a key consideration for moored vessels as well.

The overall hull form and draft are key factors with respect to the vessel's ability to clear ice and the potential for ice interference with its mooring and riser systems. Clearly, well-designed thruster systems are helpful to enhance ice clearance around a moored FPSO vessel or tanker. Especially for an azimuth thruster, it could assist both vessel's vanning response and ability to resist ice and other environmental forces. The configuration of the thrusters needs to be taken into consideration, which is expected to reduce ice resistance and ice impact on propellers. Good configuration will improve overall thrust efficiency of the vessel and save power. Moreover, any FPSO vessel or tanker that is used for ice operations should be structurally capable of sustaining the relatively high local ice pressures that may be experienced, particularly in heave ice, mixed ice and wave conditions, and small glacial ice.

Mooring and Riser Systems

Generally speaking, a vessel's mooring system should be strong enough to withstand relatively large ice forces, making sure that the vessel could maintain its position within an acceptable offset.

The overall mooring loads and individual mooring line tensions are of obvious importance and should not be exceeded. In the Arctic area, the drifting ice is changing direction frequently. Therefore, the mooring system is required to afford sound vanning capability to the vessel, which makes the vessel head toward to the new ice drift direction smoothly. During this process, the ability for riser system to track vessel motions with allowable offsets and stress levels is also important and should be taken into consideration.

When ice attacks the vessel from sideways, it is possible that ice floes move down the hull and become entangled with its turret, mooring, and riser systems. To avoid this potential risk, increasing the draft of the vessel preferably with some protection skirt around their submerged mooring and riser system is a reasonable solution. Ice ridge is often embedded into a level ice field. When it interacts with the moored ship, mooring lines are possible to be impacted by the keel part of the ice features. The resulting ice load and effect on the overall response of the system are also important, which endanger the safety of the mooring system. Under the condition of large ice features, the vessel has to disconnect from riser and mooring systems quickly and safely and move off location. This is one of the major challenges for most station keeping operations in pack ice.

Ice Loads and Vessel Responses

When designing a moored vessel in ice-covered waters, the ice conditions have to be determined as a basis. The ice loads and related ice-vessel interaction cases together with vessel responses to the ice loads are primary considerations. The ice management support should also be included to reduce ice load level if the ice condition is severe. Researchers have carried out a considerable amount of model testing and analytic work to give estimation on ice loads, responses, and capabilities of moored vessels in drift level or pack ice.

Ice forces, vessel's responses, and the resulting mooring forces that occur during ice interaction process with moored vessels are three key factors to be studied. Toyama and Yashima (1985) applied a numerical model and a model test to conclude that the surge response was greater at

low ice drift speeds. Sayed and Barker (2011) applied the particle-in-cell method based on a hybrid Lagrangian-Eulerian formulation to simulate the interaction between broken pack ice and a moored Kulluk platform. Aksnes (2010) presented a semi-empirical method incorporating probabilistic models based on the model test results. However, this model is limited to one-dimensional simulations in the surge direction only. Moored structures in ice conditions may be subjected to ice drift from different directions depending on variations in currents and wind. The contact geometry and thus ice failure are influenced by the different incident angles between the hull and ice motion. However, this model is limited to one-dimensional simulations in the surge direction only. Zhou et al. (2011, 2012) presented a 2D method in the horizontal plane for simulating level ice-hull interaction process, where the ice load during submersion, sliding, and accumulation were simplified based on empirical and analytical methods. The simplified numerical model was validated through full-scale measurements of a conical platform called the Kulluk.

Some researchers are interested in model tests in ice basins. A number of model tests were conducted by Comfort et al. (1982), Evers et al. (1983), and Nixon and Ettema (1988). Comfort et al. (1999) assembled an extensive set of ice model test data for floating and moored structures and presented the data in a common format to identify overall trends, and the Kulluk is also included as a typical structure. Recently, Aksnes et al. (2008) and Bonnemaire et al. (2008) carried out ice model tests of an Arctic Tandem Offloading Terminal with a focus on mooring forces in level and ridged ice. Later, Aksnes et al. (2010) and Bonnemaire et al. (2010) conducted ice basin tests on a moored offloading icebreaker in variable ice drifting directions. Zhou et al. (2013a) performed a series of ice model tests to investigate the ice load experienced by an icebreaking tanker. The tanker was towed through the unbroken ice sheet to simulate the interaction process. Then the ice loads were measured. Zhou et al. (2013b) applied a numerical model to simulate the dynamic ice loads acting on the

icebreaking tanker Uikku in level ice, considering the action of ice in the vicinity of the waterline caused by breaking of intact ice and the effect of submersion of broken ice floes. The numerical simulations were also compared with the measured data as given in Zhou et al. (2013a). Good agreement was achieved though there are some deviations between predicted and measured results for some cases due to uncertainties from input factors.

Conclusion

To sum up, moored ships have been widely used in ice-infested waters for many kinds of polar activities. The interaction between moored structures and ice is a complex process which is difficult to predict theoretically. Due to severe ice conditions, the structures may experience much downtime which is not desirable. How to ensure the overall safety and extend ice operation season for moored ship remains a challenge to industrial and academic worlds of polar engineering. Some main aspects for designing a moored vessel operating in icy waters could be taken as a reference in this chapter.

Definition

The passive mooring is the most commonly adapted station keeping method for offshore

floating facilities. An offshore mooring system usually consists of one or multiple mooring lines that connect the floater to the seabed to retain floater's position and limit offset to enable designated operations in various environments and water depths.

A mooring system is made up of mooring lines, anchors, and connectors, and the mooring line connects the floater to the seabed with its lower end terminate at the anchor at sea floor. The anchor is a physical device that is connected with the mooring line and penetrates into the seabed soil to hold the mooring line into position (Ma et al. 2019).

The mooring system is designed to withstand the environmental loads and operation loads in an offshore environment. Thus, the anchor holding power is a critical link of mooring system strength.

Historical Development

The history of the anchor dates back millennia. The most ancient anchors were probably made of rocks to hold ship at sea. However, using pure mass to resist the forces of a storm only works well in certain situations. Originated from anchor of rocks, advances in craftship and metallurgy encouraged development of improved shapes for more compact, durable, and efficient anchors. The modern navigation uses metal device with efficiently designed shape to connect a vessel to the seabed to prevent ship from drifting due to wind, waves, and current.

Over the years, the anchor technology has been continuously developed. The anchor design takes into account the soil resistance data and the requirements of horizontal and vertical holding capacities for safe mooring application.

For certain marine application, continuous deploying and retrieving anchors is an operation requirement, and anchors that were designed for such function have been developed.

Nowadays there are the following main types of mooring anchors (Vryhof 2015):

1. Drag embedment anchor
2. Vertical Loaded Anchor

3. Gravity installed deep penetration anchor
4. Pile anchor
5. Suction anchor
6. Gravity anchor

Working Principles of Anchors

The working principle of anchor is through its own weight or penetration into the seabed to interact with the soil to generate holding capacity. Therefore, there are two primary factors for anchor design.

1. Structural factor that is the material and shape of the anchor should have adequate strength and life expectancy
2. Geotechnical factor that is the soil characteristics, anchor size and depth of penetration should generate sufficient holding capacity

Drag Anchor

A drag embedment anchor (DEA) is the most utilized anchor for mooring floating MODUs. The drag anchor is dragged along the seabed until it penetrates the required depth. As it penetrates the seabed, it uses soil resistance to hold the anchor in place. The drag embedment anchor is mainly used for catenary moorings, where the mooring line arrives on the seabed horizontally. It does not perform well under vertical forces (Ozmutlu 2012) (Figs. 1 and 2).

The main advantage of the drag embedment anchor is it is highly mobile and can be deployed and retrieved without using heavy marine equipment. The main drawback is that the anchor's final position is less predictable which would be a problem for permanent mooring systems.

Additional features of drag anchors include:

- Standard off the shelf equipment
- Wide range of anchor types and sizes
- High capacity (greater than 100,000 lb)
- Performs poorly in rock seafloors
- Lower resistance to uplift loading
- Holding power highly directional

Mooring Anchor,**Fig. 1** Drag embedment anchor (Courtesy of Vryhof)**Mooring Anchor, Fig. 2** Drag anchor during installation. (Courtesy of Vryhof)

There are many designs and brands of drag embedment anchors. Following is a brief summary on a few well-known anchor types and their specific uses.

- The Stevpris New Generation accommodates the widest range of soils possible and its holding power is more than 30% higher than any other existing drag anchor.
- Stevpris Mk 5 is easy to handle, install, and retrieve and is used to secure semi-submersible rigs and permanent installations.
- The Stevshark Mk 5 does well in hard soils such as limestone, calcarenite, very dense sands, and coral.
- The Stevin Mk 3 was the original anchor design for Vryhof and outperformed all existing anchors at the time of its inception.
- The Bruce Mk 4 Twin Shank offers a choice of fluke angles for superior holding power in all

types of seabeds. It also has self-righting ability, even when it lands upside down.

- The Flipper Delta has an open construction for smooth penetration in different kinds of soil and no rotation, which means no decrease of holding capacity and no dragging of the anchor.
- Danforth is used for boats up to 27 ft. The I-beam fluke construction provides exceptional holding power.

The anchor holding capacity of drag embedment anchor is function of soil conditions, anchor type, anchor size, and fluke/shank angle setting. Designers often reply upon anchor capacity chart to select the suitable anchor (Fig. 3).

Vertical Loaded Anchor

The conventional drag embedment anchor does not perform well with vertical mooring load.

Mooring Anchor, Fig. 3 Anchor holding capacity. (Courtesy of Vryhof)

However, development has been made of Vertical Loaded Anchor (VLA) which would allow certain amount of mooring vertical toad. Vertical load anchors are similar to drag anchors as they are installed in the same way. However, the vertical load anchor can withstand both horizontal and vertical mooring forces. It is used primarily in taut leg mooring systems, where the mooring line arrives at an angle the seabed.

For example, the Stevmanta Vertical Loaded Anchor (VLA) allows uplift at the anchor point, which is a requirement in semi-taut and taut leg mooring systems. Its main features include: deep penetrating anchor in soft soils, suitable for supporting large vertical and horizontal loads, easy installation like a conventional drag embedment anchor and loading in all directions possible (Fig. 4).

Mooring Anchor, Fig. 4 Stevmanta vertical loaded anchor. (Courtesy of Vryhof Anchor)

SEPLA Anchors

The patented SEPLA was introduced in 1997. It was a revolutionary concept for deepwater moorings that combines two proven anchoring concepts (i.e., suction installed piles and plate anchors capable of resisting vertical loads) to increase the accuracy of anchor positioning and burial depth for preset moorings. It gave the

industry a way of realizing the holding capacity of a suction installed anchor pile without the higher cost.

SEPLA anchors are believed to be more geo-technical efficient than the suction piles that are commonly used to withstand vertical loads. The SEPLA plate anchor is fully embedded in deeper, higher strength soil layers with all components

Mooring Anchor, Fig. 5 SEPLA anchor. (Courtesy of OnePetro)

actively resisting the mooring loads. On the other hand, a large part of a suction pile's structure is in shallower, weaker soils and does not contribute much to the holding capacity (Fig. 5).

Torpedo Anchors

Torpedo piles, essentially gravity-embedded cylindrically shaped projectiles, are used to anchor deepwater flowlines and facilities offshore. Torpedo piles typically range in size from 24 to 98 tons, and the largest torpedo pile can provide an anchor-holding capacity of up to 1000 tons (Fig. 6).

Pile Anchor

For mooring situations that the accurate positioning of the anchor is important, there is presence of vertical mooring load, the seabed surface soil consists of soft soil, and the drag embedment anchor becomes unsuitable. One possible alternative is to use pile anchor made of tubular steel pipe which is driven by underwater hammer to the desired penetration below the seabed surface. The mooring line is connected to the pile anchor through a bracket prewelded before pile installation (Fig. 7).

The behavior of a pile under lateral and axial loading interacting with the seabed soil is analyzed to determine the optimal length and diameter of the anchor pile, the position of the bracket along the pile, and the depth below the mudline to which the pile should be driven. Anchor piles generate lateral capacity through passive resistance of the soil bed and axial

Mooring Anchor, Fig. 6 Torpedo anchor. (Courtesy Deep Sea Anchors)

capacity by friction or adhesion along the pile shaft. In most cases, the mooring line connection is located below the top of the pile and it can vary from $\frac{1}{2}$ to $\frac{1}{3}$ of pile penetration.

The most common piles are long slender tubular piles (L/D ratio $> \sim 10$), which are typically fabricated from rolled steel sections. Diameters are in the range of 2 – 8 feet for the large mooring systems.

During installation, the pile is first lowered on the seafloor using a crane and gradually penetrates under the self-weight through a guide frame. The driving head is installed on top of the pile and underwater hammer is used to drive the pile to its design depth. When the seafloor is rock or composed of thin sediment over rock then piles cannot

Mooring Anchor,
Fig. 7 Pile anchor
 deployment. (Courtesy of
 InterMoor)

be installed by driving. In this case, an oversize socket must be predrilled for a pile to be inserted and grouted in place.

The key features of pile anchor include:

- High lateral capacity achievable
- Resists high uplift load
- Performs well on substantial slopes
- Suitable hard seafloors (rock and coral) by drilling and grouting
- Need quality site soil data
- Installation cost high

Suction Anchor

The suction pile is a relatively new type of anchor system. It is made of tubular steel pipe with sealed top and is driven into the seabed using pump to suck out the water from the top of the tubular, which creates negative pressure inside the pipe. The application has been growing steadily in the offshore industry particularly for soft soil in deep water. Suction piles can be installed from a single workboat making installation quick, relatively inexpensive, and less weather dependent than for driven or drilled piles.

Suction piles can be more expensive to fabricate since they are welded construction but they are easier and cheaper to transport. Suction piles

employ a lower slenderness ratio (length/diameter) than tubular piles. They are shorter and with larger diameter, ranging up to 10 m for soft soil. There are a number of suction pumps available including some that are operable by a remotely operated vehicle (ROV) a capability that provides flexibility in installation. An important feature of suction piles is their ability to be extracted and recovered by reversing the pump to apply pressure inside the pile (Fig. 8).

Suction piles are the predominant mooring and foundation system used for deepwater development projects worldwide. Suction piles can be used in sand, clay, and mud soils, but not gravel, as water can flow through the ground during installation, making suction difficult. They are also effective in normal sand seafloors but are not appropriate for hard bottom conditions. Once the pile is in position, the friction between the pile and the soil holds it in place. It can resist both vertical and horizontal forces.

The key features of suction pile anchors include:

- Requires less specialized installation equipment
- High lateral and vertical capacity
- Needs extensive and better quality soil data

Mooring Anchor,
Fig. 8 Suction pile anchor.
 (Courtesy of Drill
 Formulas)

Mooring Anchor,
Fig. 9 Gravity anchor.
 (Courtesy of Subcon)

- Removable by reversing installation pump
- Cost competitive installation

might provide the only reasonable anchoring option (Fig. 9).

The main features of gravity anchors include:

Gravity Anchor

A gravity anchor is made of heavy object placed on the seafloor to resist vertical and/or lateral loading. It is typically fabricated from concrete and steel and configured to enhance lateral capacity.

Gravity anchors are often used because they are inexpensive and readily sized for most seafloor and loading conditions. Especially there is less requirement of anchor position accuracy and lack of specialized installation equipment. In general, they are not very efficient (ratio of holding capacity to weight) compared to the other anchor types. They may require heavy lift capabilities for installation and they are a poor choice on sloping seafloors. However, on very hard bottoms they

- Resist large vertical load
- Reliable holding capacity
- Simple on-site construction
- Material readily available and economical
- Reliable on thin sediment over rock
- Not suitable in seafloor slope
- Size limited by load handling equipment
- Lateral load to weight ratio is low

Key Applications

Since the anchor connects the mooring line to the seabed, it is a critical component for the integrity of mooring system. The various anchor types find

their applications in different types of mooring systems.

For permanently mooring systems, the suction pile and driven pile are most commonly used for its reliability and location accuracy. The high-efficiency drag anchor and VLA have also been used for small floating units under mild environment.

For drilling operations with MODUs, the drag anchors are most commonly used for easy deployment and retrieval without specialized facilities. However, they have limited capability to withstand vertical loads. VLAs are the alternative where high vertical loads at anchor are present. Driven pile or suction pile are only used under special conditions such as very high vertical load or anchor movement strictly prohibited. Because of the temporary nature of the operation, a thorough soil investigation is normally not conducted, which makes the anchor design more challenging.

Torpedo pile and gravity-installed anchor are relatively new anchor concepts, which have been used in MODU and permanent moorings. The anchor design requires the full range of geotechnical analysis.

In situations where penetration into the seabed is not possible, for example, rock seabed, dead weight anchors made of reinforced concrete or scrap steel may be used. Vertical capacity is simply the submerged weight of the anchor.

Definition

The passive mooring is the most commonly adapted station keeping method for offshore floating facilities. An offshore mooring system usually consists of one or multiple mooring lines that connect the floater to the seabed to retain floater's position and limit offset to enable designated operations in various environments and water depths.

A mooring line consists of line segments of different materials, such as chain, wire rope, and polyester. The connector is a physical device that connects different line segments and anchors.

The mooring system is designed to withstand the environmental loads and operation loads in an offshore environment. As part of the strength-carrying element, the connectors shall have compatible breaking load as other mooring components (API 1981).

Historical Development

The traditional mooring line for station keeping of ships in harbor was typically made with chain of uniform size. As the offshore moorings evolved, mooring systems become more complex with mooring lines made of different segments to achieve the desired performance characteristics. As such, a mooring line usually consists of a number of segments with different materials such as chain, wire rope, polyester, etc. Even if a mooring line is made of a single type of material, the line may be segmented for the purpose of transportation and installation. Therefore,

connectors are used to connect the various mooring line segments.

There are many types of connectors for connecting different types of mooring components. The commonly used ones include D-shackles for connecting the chain segments, D-shackle in association of wire rope termination for connecting the chain to wire rope, H-link for connecting the chain to polyester segment, etc. (Ma et al. 2019).

Working Principle

Since the connector is a load-carrying link within a mooring line, the strength and design life of the link must be compatible with those of mooring line segments to maintain the basic integrity and reliability of the complete mooring line. The design of the mooring link should take the following factors into consideration:

- Adequate strength
- Adequate fatigue life
- Physically compatible with segment terminations
- Ease of connection and disconnection

For permanent mooring systems, D-shackle and H-link are the two most commonly used

Mooring Connector, Fig. 1 Common D-shackle. (Courtesy of Zhengmao)

types for connection among the chain, wire rope, and polyester. Because inspection and replacement of connectors in a permanent mooring are difficult and costly, their designs need to be robust with adequate fracture toughness, fatigue life, and corrosion resistance. Manufacturing of connectors should be subject to an appropriate level of quality assurance corresponding to the same level as those of mooring chain.

Applications

D-Shackle

The D-shackle is most commonly used for joining the adjacent chain segments. It consists of a bow,

Mooring Connector, Fig. 2 Common D-shackle measurement. (Courtesy of Sotra Marine)

Mooring Connector, Fig. 3 Wire rope termination. (Courtesy of Lebeon)

which is closed by a pin with single or double locking nut. The pin can be of rounded shape or oval shape depending on the purpose of application (Fig. 1).

The shackle is made by forging and with corresponding grade as per chain links. D-shackle can be used in both temporary and

permanent moorings. The dimensions of the D-shackle are standardized as illustrated by the sketches below (Fig. 2).

D-shackle can also be used to connect chain segment to wire rope in association of the closed or open socket termination of the wire rope (Fig. 3).

Mooring Connector,

Fig. 4 Anchor shackle measurement. (Courtesy of Sotra Marine)

M

Mooring Connector, Fig. 5 H-link. (Courtesy of Vicinay)

Mooring Connector, Fig. 6 H-link in polyester connection. (Courtesy of Oceanside Equipment)

Anchor Shackle

Anchor shackle is another type of D-shackle that connects the chain segment to the mooring anchor. Like a common D-shackle, it consists of a bow, which is closed by a pin with single or double locking nut. The pin is of rounded shape for free rotation.

This type of D-shackle is made by forging and with corresponding grade as per chain links. It can be used in both temporary and permanent moorings. The dimensions of the anchor shackle

are also standardized as illustrated below (Fig. 4).

H-Link

The H-link is commonly used in mooring lines for connecting segments of the line. This type of connector has been traditionally used for connecting chain segments. Lately the H-link is introduced to connect polyester rope with chain segment. The main feature is to avoid time-consuming handling of bulky thimbles for the

Mooring Connector,

Fig. 7 Kenter link and application. (Courtesy of Sotra)

eyes of polyester ropes. They can also be used to connect two lengths of polyester ropes in deepwater mooring lines (Figs. 5 and 6).

Kenter Link

The connecting kenter-type link is most commonly used for the connection of two pieces of chain mooring line, where the terminations of the two pieces have the same dimensions. It has the same outside dimension as a chain link of the same diameter. It therefore allows the connected chain piece going through mooring devices such as fairlead, chainstopper, windlass, etc. The kenter link is commonly used to connect chain of mobile offshore drilling units which require frequent handling of mooring lines. Generally speaking, the kenter link is not used in permanent mooring systems, first because the frequent line handling is not a requirement and second, the kenter link has a shorter fatigue life than the chain of compatible strength.

The kenter-type joining link contains three parts along with taper pin and lead plug. The two main halves have numbers to be matched and arrows to be lined up for ease of assembly with the third piece (stud). The two main parts are attached to the ends of the chain in a vertical position and then fitted together, and the stud is then slid into place, which locks the link. The stud is secured by hammering a tapered pin into the hole drilled diagonally through all three parts of the joining link (Fig. 7).

Pear Link

The pear-shaped connecting link is, in essence, similar to kenter link and C-link, except that it is used for the connection of two pieces of mooring chain with different dimensions. Like kenter link and C-link, the pear-shaped connecting links are not used in permanent mooring systems.

Note there is a product called trident link that combines the features of kenter and pear links. Trident link is mainly used to connect an anchor shackle directly to a chain, thus reducing the amount of required connections. In this way, it is very similar to a pear Link with the only notable differences being the method of assembly. This type of shackle can also be used in a variety of

other applications where the crossover from one size to another is required.

The pear link is often used during offshore installation, for example, where a smaller piece of line is connected to pull in the pre-laid mooring lines (Fig. 8).

C-Link

Like the kenter link, the connecting link C-type is used for the connection of two pieces of mooring chain with terminations that have the same dimensions. The major difference between the kenter type and the C-type is the way that the connector is opened and closed (Fig. 9).

Mooring Connector, Fig. 8 Pear link. (Courtesy of Vryhof)

Mooring Connector, Fig. 9 C-Link. (Courtesy of Vryhof)

Mooring Connector, Fig. 10 Swivel link. (Courtesy of Zhengmao)

twist and torque that builds up in the mooring line (Fig. 10).

The swivel can be placed at various locations along the mooring line. There are many different types of swivels available. One of the main design concerns is that when loaded, the swivel link may lock up due to the high friction inside the turning mechanism. Some newly designed swivels are fitted with bearing to enable swiveling under load.

Triplate

Mooring triplate can also be used in association with D-shackles to connect the mooring line segment. It is often used for handling during mooring installation (Fig. 11).

Introduction

Mooring lines provide the connections between floating facilities and anchoring foundations embedded in the seabed and are used for station keeping of floating facilities. Mooring line is

normally made up of steel chain links, wire ropes, and synthetic fiber ropes or a combination of the three.

In shallow water zone including rivers and lakes, mooring lines are used for limiting the shift of boats and barges, as shown in Fig. 1a. The most common choice for mooring line component is usually chain. In most practices, single line mooring is the most popular mooring pattern, where two-line mooring is also widely used. In offshore oil and gas industry, mooring lines are used for limiting the movement of offshore vessels and platforms to control the offset of risers and drill pipes connected to these floating facilities. The mooring patterns in deep water are usually using groups of mooring lines (see Fig. 1b), which can adopt a spread mooring, single point mooring, or turret mooring. Steel wire rope is a better choice in water depths between 300 and 2000 m due to its lighter weight and higher elasticity than chain. In ultra-deep water greater than 2000 m, multicomponent mooring line is

generally used, which is a combination of chain, wire rope, and synthetic fiber rope.

Mooring lines, functioning as a station-keeping component of an anchoring system, play the crucial role in safe operation of the moored floating facilities. The floating facilities would be out of control in case of failure of the mooring lines, which may cause serious casualties, property losses, and damage to marine environment. It is significant to understand the behaviors and failure mechanisms of mooring lines.

This entry is to provide readers with a general introduction of mooring lines, especially for offshore practice. The content includes historical development of mooring lines, materials, configurations and layouts in industry practice, and analytical solutions of mooring line behaviors.

Performance of Mooring Lines

Historical Development of Mooring Lines

Natural fiber rope was probably human's first invention used for mooring boats and ships. Tales of early anchor chain usage come from China. Around 2200 B.C., the Emperor Yu is reported to have used "iron chains, two fore and aft, which were thrown overboard to steady and stop the vessel." However, the iron chain was hardly used to moor vessels before the seventeenth century. Natural fiber rope was still used for mooring until the nineteenth century before steel chain and wire rope eventually replaced it. Steel chain was successfully produced by electric welding after World War I, which contributed to the rapid and wide spreading of chains. Synthetic fiber materials, including nylon, polypropylene, polyester, aramid, and polyethylene, were introduced into marine mooring around the mid-twentieth century (Flory et al. 2015). Nowadays, synthetic fiber ropes are becoming a promising alternative to wire ropes in many mooring applications, especially for oil production platforms in deep water.

As the offshore oil and gas industry is moving toward deep water, mooring patterns including spread moorings and single point moorings were used to withstand ocean environmental load.

Mooring Lines, Fig. 1 Mooring lines in shallow and deep water. (a) Mooring line for boat, (b) mooring lines for semisubmersible

Spread moorings are mainly used for semisubmersibles and spars, while single point moorings tend to be used more for ship-shaped vessels (API 2005).

Mooring Lines Components

A mooring system comprises mooring lines, connectors, anchors, and winches or windlasses. The mooring line is usually made up of chains, wire ropes, synthetic fiber ropes, or their combination.

Chain is the most common product type used for mooring lines. There are mainly two different designs of chain, studlink and studless chain, as shown in Fig. 2a. The studlink chain is commonly used for mobile moorings where the mooring line can be reset numerous times during their lifetime, such as semisubmersibles and mobile offshore drilling units (MODUs). The studless chain is often used for permanent moorings (such as a floating production storage and offloading (FPSO)) with design lives over 10 years. The studless chain has lower weight per unit of strength and less manufacture expense than the studlink chain.

Wire rope is made up of individual wires wound in a helical pattern to form a “strand” (Brown 2005). The types of wire rope used as mooring line include multistrand and single-strand rope. Multistrand wire rope, also called stranded rope, consists of a number of strands wound in the same rotational direction around a center core to form the wire rope (DNV 2013). The center core may be either a fiber or a metallic core to support the outer wires. As shown in Fig. 2b, six-strand rope is the most common type of multistrand rope and often used for temporary mooring. Single-strand rope, also called spiral rope, uses bundles of wires wound in opposing

directions to obtain the torque-balanced characteristics. Single-strand rope has longer fatigue life than the multistrand rope and thus is more commonly used in permanent mooring.

Typical materials of synthetic fiber rope that are currently used for mooring are polyester and high modulus polyethylene (HMPE), as shown in Fig. 2c. High-performance fiber rope materials, including aramid, HMPE, liquid crystal aromatic polyester (LCAP) fiber, and so on, have been introduced into the mooring since the mid-1960s. The major advantages of synthetic fiber ropes are their light weight and elasticity of the material (Vryhof Anchors 2015). The synthetic fiber ropes are usually employed with combination of chain and wire rope in deep water. During deployment, it is normally not permissible for fiber rope to contact with the seabed unless specifically qualified, because the ingress of foreign particles such as sand will affect the rope’s yarn-on-yarn abrasion resistance and hence will adversely affect the rope’s fatigue life (DNV 2008).

Connectors

Connectors are the components to be used to connect two different segments of a mooring line or a mooring line to vessels or to padeyes on anchors. Typical connectors include Kenter shackle, D-shackle, C-link, pear link, and swivel, as shown in Fig. 3.

Mooring Configurations in Water Column

Mooring configurations can be catenary, taut, or semi-taut line or vertical moorings, as shown in Fig. 4.

A catenary mooring configuration presents a mathematical catenary curve between the

Mooring Lines, Fig. 2 Mooring lines components. (a) Chain, (b) wire rope, (c) HMPE rope

Mooring Lines, Fig. 3 Typical connectors. (a) Kenter shackle, (b) D-shackle, (c) C-link, (d) pear link, (e) swivel

Mooring Lines, Fig. 4 Mooring configurations. (a) Catenary mooring, (b) taut line mooring, (c) semi-taut line mooring, (d) vertical mooring

floating facility and the seabed. The mooring line is suspended from the floating facility and touches down on the seabed. Therefore, an obvious characteristic of catenary mooring line is part of the mooring line lays on the seabed. During operation, most of the restoring forces to the floating facility are generated by the weight of the mooring line (Randolph and Gourvenec 2011).

Compared with the catenary mooring that arrives at the seabed horizontally, a taut or semi-taut line mooring arrives at the seabed at an angle, resulting in both horizontal force and vertical force to the anchor. The restoring forces of the taut line are mainly generated by the elasticity of the mooring line. Synthetic fiber ropes that mainly include polyester ropes and polyethylene ropes are often used in taut line moorings. An advantage of a taut

line mooring superior to the catenary mooring is its shorter line length and smaller seabed footprint, which means the spread radius of taut line mooring is smaller than that of catenary mooring for a similar application. Semi-taut line moorings provide a greater seabed footprint than taut line moorings but reach similar maximum angles under critical design conditions (Randolph and Gourvenec 2011). Typical horizontal distance from the touch-down point normalized by the water depth ranges from 1 for taut line mooring, to 1.5 for semi-taut line mooring, and to 2 for catenary mooring.

Vertical moorings or tendon/tension leg moorings are used to anchor large production units, such as tension-leg platforms, in very deep water. Recently, vertical moorings are also used in small floating units.

Offshore Mooring Systems Layout Patterns

Offshore mooring systems can be classified into spread mooring, single point mooring, and dynamic positioning.

A spread mooring system consists of a group of mooring lines symmetrically distributed to the longitudinal center line of the platforms or vessels. The symmetrical arrangement of anchors keeps the heading of floating facilities being essentially fixed and prevent the rotation in the horizontal plane due to wind, waves, or current.

Figure 5 shows some typical offshore mooring patterns: Fig. 5a, b shows the patterns often used by vessels like drillship and FPSO, Fig. 5c shows the pattern used by the semisubmersible, and Fig. 5d shows the pattern used by a spar platform. Spread mooring is versatile because it can be applied to most vessels in varying water depth. However, large loads can be caused on the mooring line in ocean environment.

Single point moorings connect all the mooring lines to a single connection point that can be a

Mooring Lines, Fig. 5 Typical spread mooring (plan view). (a) Vessel mooring (ten lines), (b) vessel mooring (eight lines), (c) semisubmersible mooring, (d) spar mooring

Mooring Lines, Fig. 6 Single point moorings. (a) Turret mooring, (b) CALM, (c) SALM

buoy body or turret or tower. The vessel can rotate freely (i.e., weathervane) around the single point with the environment loads. There is a wide variety in the design of single point moorings, which typically include turret mooring, catenary anchor leg mooring (CALM), and single anchor leg mooring (SALM), as shown in Fig. 6.

A turret mooring system connects a turret assembly of a vessel, generally FPSO or floating storage and offloading (FSO), to the seabed by means of the mooring lines. The turret system that is fully passive contains a bearing system allowing the vessel to rotate around the fixed geostatic part of the turret. The turret mooring system is considered to be more economic and reliable and is widely used today.

The turret can be located externally or internally with respect to the vessel hull structure. For the external turret mooring system, the turret is located at the extreme end of an outrigger structure attached to the bow of the vessel. For the internal turret mooring system, the turret is integrated into the hull structure at the bow of the vessel, as shown in Fig. 6a.

Disconnectable turret mooring system has also been developed to further reduce the environmental loading on the mooring system in extreme conditions. The disconnectable turret uses a buoy that is located at the lower end of the turret. In a harsh ocean environment, the buoy can break away from the vessel and can still provide support to the risers and mooring.

The catenary anchor leg mooring (CALM) (sometimes called a single buoy mooring) consists of a large buoy held in place by a number of catenary mooring lines anchored to sea floor

(Olsen 2007). The vessel is fastened to a turntable or platform on the deck of the buoy through a hawser that is typically synthetic rope, or rigid arm or soft yoke system, so that the vessel can rotate around the buoy. The vessel can be easily evacuated from a harsh environment by unfastening the connections between the vessel and buoy.

For the single anchor leg mooring (SALM), a buoy under or on the water surface is anchored to an anchor point or base by a mooring line (taut wire rope or vertical chain), which is tensioned to pull the buoy against its buoyancy. The restoring force of the system comes from the buoyancy force of the buoy and the elasticity of the mooring line. The buoy is connected to the vessel through a hawser or yoke. In Fig. 6c, an underwater hose rises from the fluid swivel at the base or at a point above the base to the sea surface at a point away from the buoy for some distance.

Basic Mechanics of Mooring Lines

The mooring line of a vertical mooring is attached to the top of an anchoring foundation, and the one-dimensional responses of the mooring line in water are relatively easy to be analyzed. For catenary and taut line moorings, the behavior of the mooring line in water can be analyzed by solving the differential equations governing the segment of the line in water column. For catenary and taut line moorings using anchor piles, suction caissons, or drag anchors, the optimal attachment point of the mooring line is below the mudline. Therefore, it is essential to consider the performance of the anchor line in soil, which forms an inverse catenary shape due to soil resistance acting on the line. The behavior of embedded anchor line can be described by

solving the differential equations governing the segment of the line in soil.

Behavior of Mooring Line in Water

A mooring line element is shown in Fig. 7. The differential equations governing the segment of the line are:

$$(T + dT) \cos(\theta + d\theta) - T \cos \theta = 0 \quad (1)$$

$$(T + dT) \sin(\theta + d\theta) - T \sin \theta - wdl = 0 \quad (2)$$

where T is the line tension, θ is the angle between the tension and horizontal direction, w is the submerged line weight per unit length, and l is the distance along the line. Provided that a mooring line is single-component (the submerged line weight per unit length is constant) and the elastic stretch is ignored, as shown in Fig. 8, the equations below can be obtained:

$$T_x = T_0 \cos \theta_0 = T_p \cos \theta_p \quad (3)$$

$$T_p = T_0 + wh \quad (4)$$

$$\begin{aligned} h &= \left(\frac{T_0}{w}\right) \\ &\times \left[\sqrt{\tan^2 \theta_p + 1} - \sqrt{\tan^2 \theta_0 + 1} \right] \\ &= \left(\frac{T_0}{w}\right) \left(\frac{1}{\cos \theta_p} - \frac{1}{\cos \theta_0} \right) \end{aligned} \quad (5)$$

Mooring Lines, Fig. 7 Force equilibrium of an inelastic mooring line element in water

$$S = \left(\frac{T_0}{w}\right) [\sinh^{-1}(\tan \theta_p) - \sinh^{-1}(\tan \theta_0)] \quad (6)$$

$$l = \left(\frac{T_0}{w}\right) (\tan \theta_p - \tan \theta_0) \quad (7)$$

where the T_0 and T_p are the tensions at the touch-down point and top of the mooring line, respectively; T_x is the horizontal component of T_0 ; θ_0 and θ_p are the angles between the horizontal direction and the tension T_0 and T_p , respectively; h is the vertical distance from the touch-down point; and S is the horizontal distance from the touch-down point.

When $\theta_0 = 0$, the mooring state becomes the catenary mooring, and the following equations can be obtained:

$$\tan \theta_p = \frac{wl}{T_0} \quad (8)$$

$$T_p = T_0 + wh = T_0 + \sqrt{(wl)^2 + T_0^2} \quad (9)$$

$$\begin{aligned} h &= \left(\frac{T_0}{w}\right) \left[\sqrt{\tan^2 \theta_p + 1} - 1 \right] \\ &= \left(\frac{T_0}{w}\right) \left[\cosh\left(\frac{wS}{T_0}\right) - 1 \right] \end{aligned} \quad (10)$$

Mooring Lines, Fig. 8 Forces acting on inelastic mooring line in water

$$S = \left(\frac{T_0}{w} \right) \sinh^{-1} (\tan \theta_p) \quad (11)$$

A typical mooring line is usually multi-component line made up of connectors, wire rope, polyester rope, and chain. For the multi-component line, the tangential slopes of two components at the connectors are treated to be equal in order to solve the equations.

Behavior of Embedded Anchor Line in Soil

As shown in Fig. 9, the anchor line inclination at the attachment point of anchor or pile is critical in the design, because it will determine the mode of failure for anchor pile or suction caisson and the embedment performance of drag anchors.

Figure 10 shows the force equilibrium of a segment of anchor line. The differential equations governing the embedded segment of the anchor line are (Randolph and Gourvenec 2011)

Mooring Lines, Fig. 9 General configuration of anchor pile and embedded anchor line

Mooring Lines, Fig. 10 Force equilibrium of an embedded anchor line element

$$\frac{dT}{dl} = F + w \sin \theta \quad (12)$$

$$T \frac{d\theta}{dl} = -Q + w \cos \theta \quad (13)$$

where F is the soil friction (per unit length, parallel to the line) acting on the segment of the line, Q is the soil resistance (per unit length, normal to the line) acting on the segment of the line.

The soil friction F and normal soil resistance Q can be expressed as

$$F = A_s \alpha s_u \quad (14)$$

$$Q = A_b N_c s_u \quad (15)$$

where A_s is the effective surface area of the anchor line per unit length, α is the interface friction coefficient (typical values of α in clay range from 0.2 to 0.6 depending on whether wire rope or chain is used), s_u is the undrained shear strength, A_b is the effective bearing area of the anchor line per unit length, and N_c is bearing capacity factor. For wire rope, A_b is equal to the diameter of the rope d and $A_s = \pi d$. For a standard link chain, $A_b = 2.5d$ and $A_s = 8-11d$.

Neubecker and Randolph (1995) proposed a simplified analytical solution of an embedded anchor line, in which the self-weight of the anchor line is ignored. The analytical solutions are expressed as

$$\frac{T_a}{2} (\theta_a^2 - \theta_0^2) = \int_0^{z_a} Q dz = z_a Q_{av} \quad (16)$$

$$\frac{T_0}{T_a} = e^{\mu(\theta_a - \theta_0)} \quad (17)$$

where T_a is the embedded anchor line tension at the attachment point, θ_a is the embedded anchor line inclination at the attachment point, z_a is the depth to the padeye, Q_{av} is the average bearing resistance over the depth range of 0 to z_a , and μ is the friction coefficient and calculated by F/Q .

Synonyms

Dynamic positioning system; Single point mooring; Spread mooring

Definition

A mooring refers to any permanent structure to which a floating structure may be secured. Examples include quays, wharfs, jetties, piers, anchor buoys, and mooring buoys. A floating platform is secured to a mooring to forestall free movement of the structure on the water. An anchor mooring fixes a floating structure's position relative to a point on the bottom of a waterway without connecting the structure to shore. The mooring systems are usually composed of anchors, mooring lines, buoy, and connectors.

Scientific Fundamentals

Mooring system and dynamic positioning system are the two main methods to keep a floating structure positioning. They can be used with either ship-shaped or offshore floating structures.

Since ancient times, mooring system has been a traditional positioning way. Mooring system for ships is generally used to meet the needs of temporary berthing and prevents the ship from drifting freely on the water surface. It is mostly used in storm-free shallow water areas. Mooring system is also the most commonly used passive positioning form for offshore platforms. Considering severe ocean environment and the positioning requirements of deepwater drilling and production platform, the research, design, and manufacture of deepwater structure mooring system is so challenging that once become a technical bottleneck for deep-sea oil and gas exploitation. The research and development of mooring forms and mooring materials have been progressing steadily. Mooring ways change from traditional catenary mooring to tension mooring used in drilling and mining platform, such as SPAR and TLP platforms. Traditional high-quality mooring chains and wires are increasingly unable to meet the needs of the development of deep-sea drilling and mining, and the research and development of new mooring materials have been conducted (Luo 2015).

Usually there are three kinds of mooring systems according to the different positioning time. The mobile mooring system is used for pipe laying ship, lifting ship, and so on. Temporary mooring system is used for drilling ship or drilling platform. Permanent mooring system is used for the production of variety of floating platforms and FPSOs.

Mooring system can also be divided into catenary mooring system and tension mooring system according to the shape of mooring line. The former is mostly used for moderate depth and shallow water, and the latter has smaller mooring radius, length, and load than the former. Catenary mooring system is a traditional deployable mooring system. It has a long history and can adapt to harsh marine environment. It still plays an important role in current positioning technology of deepwater offshore oil and gas platforms. Tension mooring system is gradually developed with the application of fiber materials in deep sea. It was first applied to the tension leg platform and Spar platform in the 1980s.

According to the arrangement of lines, there are single point and spread mooring system. The former is mostly used for ship-shaped platform. In 1959, the first set of CALM (Catenary Anchor Leg Mooring) system designed by American IMODCO Company was successfully made in Sweden. It unveiled the prelude to the application of single mooring technology in offshore oil exploitation and offloading. From 1976 to 1985, single point mooring for FPSO experienced the initial mooring development phase of offshore oil and gas production. Single mooring technology welcomed its growth stage from 1986 to 1994, and extension stage from 1995 to 1998. Since 1999, the number of FPSO has increased rapidly. Major breakthroughs of mooring technology have been developed, especially for limits of water depth. Spread mooring is a natural extension of traditional ship mooring. It is suitable for Spar, Semi-submersible platforms, FPSO, and ship-shaped structures. And the environment conditions for spread mooring need to be moderate (Flory 2001).

In terms of mooring lines' materials, the typical materials have changed from steel chains and

wires to synthetic fibers. Steel chain is the most traditional mooring material. It has been widely used in single point and multi-point mooring of drilling and production ships and platforms since the early stage (Corbetta and Sloan 2001). Wire mooring line is made of steel wires, and its quality is lighter than steel chains, which is suitable for deeper-water mooring (Costa et al. 2001). With the development of tension mooring, synthetic mooring has become one of the key technologies of system research (Dove et al. 2000). Synthetic fiber line is usually made of polyester fiber (PET), high strength polyethylene (HMPE), aromatic nylon (Aramid), and so on, among which, polyester line is the most popular one. In the 1970s, foreign scholars began to study the traditional polyester fiber and nylon mooring lines as mooring materials. In 1996, a synthetic fiber mooring line consisting of PET, nylon, and HMPE was successfully installed on DeepStar platform. In 1997, a polyester rope + anchor chain catenary mooring system is first used for a FPSO in Brazil. Afterwards, more and more fiber mooring systems appeared in the Gulf of Mexico (Winkler and Mckenna 1994).

When oil and gas exploration and production was conducted in shallow to deep water, the most common mooring line configuration was the catenary mooring line consisting of chain or wire rope. For exploration and production in deep to ultra-deep water, the weight of the mooring line starts to become a limiting factor in the design of the floater. To overcome this problem, new solutions were developed consisting of synthetic ropes in the mooring line (less weight) and/or a taut leg mooring system (Vryhof 2005).

The major difference between a catenary mooring and a taut leg mooring is that where the catenary mooring arrives at the seabed horizontally, the taut leg mooring arrives at the seabed at an angle. This means that in a taut leg mooring, the anchor point has to be capable of resisting both horizontal and vertical forces, while in a catenary mooring the anchor point is only subjected to horizontal forces. In a catenary mooring, most of the restoring forces are generated by the weight of the mooring line. In a taut leg mooring, the restoring forces are

generated by the elasticity of the mooring line (API 2005).

Key Applications

The history of mooring system started from the development and use of the single point mooring device of catenary buoy by the US navy during World War II and then developed rapidly. Numerous different mooring systems have been developed over the years. Generally, the mooring systems are divided into single point mooring and spread mooring (DNV 2008).

Single Point Mooring

A single point mooring system connects all the lines to a single point. It links subsea manifolds connections and weather vaning tankers, which are free to rotate 360° . The single point system includes a buoy, mooring and anchoring elements, product transfer system, and other components.

Single point moorings are used primarily for ship-shaped vessels. They allow the vessel to weather vane. This is necessary to minimize environmental loads on the ship-shaped vessel by heading into the prevailing weather. There is wide variety in the design of single point moorings, such as Catenary Anchor Leg Mooring, Single Anchor Leg Mooring, Turret mooring.

CALM buoy – Generally the buoy will be moored using four or more mooring lines at equally spaced angles. The mooring lines generally have a catenary shape. The vessel connects to the buoy with a single line and is free to weather vane around the buoy.

SALM buoy – These types of buoys have a mooring that consists of a single mooring line attached to an anchor point on the seabed, underneath the buoy. The anchor point may be gravity based or piled.

Turret mooring – This type of mooring is generally used on FPSOs and FSOs in much harsh environments. Multiple mooring lines are used, which come together at the turntable built into the FPSO or FSO. The FPSO or FSO is able to rotate around the turret to obtain an optimal orientation relative to the prevailing weather

conditions. The turret can be mounted externally from the vessel bow or stern with appropriate reinforcements or internally within the vessel. The chain table can be above or below the waterline (Fig. 1).

Spread Mooring

The spread mooring system does not allow the vessel to weather vane, which means to rotate in the horizontal plane due to wind, waves, or current. Spread mooring is versatile as it can be used in any water depth, on any vessel, in an equally spread pattern or a group.

In a typical spread mooring system, groups of mooring lines are terminated at the corners of the vessel, holding a stable vessel heading. Since the environmental force on a semi-submersible or a spar is relatively insensitive to direction, a spread mooring system can be designed to hold the vessel on location regardless of the direction of the environment. However, this system can also be applied to ship-shaped vessels, which are more sensitive to environmental directions. The mooring line can be chain, wire rope, fiber rope, or a combination of the three. Either conventional drag anchors or anchor piles can be used to terminate the mooring lines (Baritrop 1998).

The catenary mooring system is the most commonly used system in shallow water. It gets its name from the shape of the free hanging line as its configuration changes due to vessel motions. At the seabed, the mooring line lies horizontally; thus, the mooring line has to be longer than the water depth. Increasing the length of the mooring line also increases its weight. As the water depth increases, the weight of the line lessens the working payload of the vessel. In that case, synthetic ropes are used. As water depth increases, conventional, catenary systems become less and less economical (ABS 2014).

The taut leg system typically uses polyester rope that is pre-tensioned until taut. The rope comes in at a $30\text{--}45^\circ$ angle on the seabed where it meets the anchor (suction piles or vertically loaded anchors), which is loaded vertically. When the platform drifts horizontally with wind or current, the lines stretch and this sets up an opposing force.

Mooring System, Fig. 1 (a) Typical internal turret mooring (b) typical external turret mooring

The semi-taut system combines taut lines and catenary lines in one system. It is ideally used in deepwater (SBM 2012).

Mooring System of Renewable Energy Devices

Zhen Gao

Norwegian University of Science and Technology, Trondheim, Norway

Definition

A mooring system is a system of several mooring lines which are connected to a floating structure of renewable energy device at one end and fixed to the sea bed at the other end, to restrict the horizontal excursions and orientation of the floating structure.

General Purpose of Mooring System

A station-keeping system (ISO 2005) is to restrict the horizontal excursions of the floating structure

within prescribed limits, as well as to provide means of active or passive directional control when the structure's orientation is important for safety or operational considerations. For floating offshore renewable energy devices, including floating wind turbines, floating wave energy converters, and floating tidal turbines, a passive station-keeping system, i.e., a mooring system, is needed to limit the offset of the floater under environmental actions of waves, wind, and current, so that the desired normal operations, i.e., power production, can be maintained, without breaking the power cable. Active station-keeping system, such as dynamic positioning system with propellers and thrusters, is not relevant for offshore renewable energy devices because of the high cost and the high electricity used to keep the floating structure in position.

A mooring system typically consists of a group of mooring lines which can be configured as spread mooring or turret (or single point) mooring. Most of the mooring systems for offshore renewable energy devices are based on spread mooring configurations, as shown in Fig. 1 for floating wind turbines. Mooring lines are slender structures of chain links, steel wire, and/or fiber ropes, which are connected to the floater at its fairlead and to the anchor on the sea bed. Mooring systems for offshore oil and gas platforms are designed with redundancy so that failure of one line will not lead to failure of the whole mooring system and will not result into a drift off of the platform. This is because the consequence of such failure might be significant in terms of not only property loss but also fatalities and environmental pollution. However, floating renewable energy devices are usually unmanned, and there are less significant consequences due to mooring failure, which is mainly property loss. Most of the mooring systems used today for floating wind turbines just have three minimum lines with no redundancy.

Depending on the way that a mooring system provides the restoring effect on floater motions, we have catenary mooring, taut mooring, and tension legs. For example, catenary moorings are suitable for spar and semisubmersible floating wind turbines, and tension legs are designed for TLP floating wind turbines, as shown in Fig. 1.

Mooring System of Renewable Energy Devices, Fig. 1

Floating wind turbines and their mooring systems (From left: spar, semisubmersible, and TLP) (Graphic by Joshua Bauer at NREL)

Catenary line is a series of chain links, and it provides the restoring effect via the change of the catenary shape under large gravity force. It has a large proportion of the line on the sea bed, to avoid a sudden increase in mooring stiffness when the whole mooring line is lifted up from the sea bed. When this happens, the stretching of the chain links will take place and give too large mooring stiffness. Taut lines of steel wire or fiber ropes and tension legs provide the restoring effect through the axial extension of the line. When a clump weight or a buoy is used, a catenary effect can be generated from the relative angles between the two segments that are connected by the clump weight or the buoy. An illustration of the different mooring configurations, typically for floating wave energy converters, is shown in Fig. 2.

For floating wind turbines in a farm configuration, it is important to reduce the footprint of each mooring system to limit the range of the offshore wind farm. Normally, catenary mooring systems have a much larger footprint as compared to the taut line or TLP systems. In a TLP platform, the pretension of the tendons is provided by the extra buoyancy force of the floater which is larger than the gravity of the whole system and should be large enough to avoid slack and large transient dynamics

in mooring tendons considering the floater motions under wind, wave, and current loads.

Mooring system has a strong influence on the motions of floating structures. It provides a restoring effect on the horizontal motions of the floater, i.e., surge, sway, and yaw, for which there is no hydrostatic restoring effect. This is particularly important for floating wind turbines, which may have significant mean thrust force on the wind turbine under normal operations and may potentially lead to a large offset of the floater. As shown in Fig. 3, the mooring stiffness is normally characterized by the (horizontal) tension-offset curve, which is typically nonlinear when the offset is large.

The stiffness of mooring lines is designed so that the natural periods for horizontal rigid-body motions of the floater are in the order of 1–2 mins, which are much larger than the main wave periods, to avoid resonance due to the first-order wave loads. However, low-frequency resonant horizontal motions can be excited by either second-order wave loads or slowly varying wind loads, which are one order of magnitude smaller than the first-order wave loads. Both catenary mooring system and deep water taut mooring system have limited influence on the vertical motion modes of the floater, i.e., heave, roll, and

Mooring System of Renewable Energy Devices, Fig. 2 Mooring configurations for floating wave energy converters with catenary line, taut line, TLP as well as with clump weights and buoys (EMEC 2015)

Mooring System of Renewable Energy Devices, Fig. 3 Typical catenary mooring system for a floating wind turbine (left, units in meters) and mooring line characteristic curve (tension-offset relationship) (right) (Xu 2015)

pitch. While tension legs in a TLP are designed with high axial stiffness so that the natural periods of the vertical motion modes are in the order of 1–3 s, which are smaller than the main wave periods. In other words, the wave-frequency motions of the floaters are not constrained in a catenary and taut line system, and the first-order wave loads are compensated by the inertia loads of the floater, while such motions in the vertical modes are constrained by the tendons in a TLP, and the first-order wave loads in these modes are taken directly by the tendons, as the restoring effect.

Mooring Line Components

Mooring lines may consist of chain links, steel wire, fiber ropes, and/or a combination of these; see Fig. 4. Chain links are welded and connected steel bars, with or without stud. In deep waters, because the total weight of chain links can be very large and have to be compensated by the additional buoyancy of the floater, they are used in combination with steel wire or fiber ropes with less weight for such conditions. Chain link has a good property against friction and abrasion and are often used at the fairlead and/or at the sea bed. Steel wire might be six-strand or spiral-strand constructions. Synthetic fiber ropes are polyester, aramid, or nylon, which are light materials and suitable for very large water depths. Chain links are normally used in a catenary mooring system. Steel wire can be used in both catenary and taut moorings, while fiber ropes are normally used for taut-line systems. A particular challenge for mooring system in shallow waters is that the mooring stiffness can increase significantly for a small

increase in the horizontal offset of the fairlead, which leads to a significant increase in mooring line tension. Therefore, clump weights or buoys might be placed in between the mooring line segments to increase the catenary effect for such conditions.

Anchors are placed at the lower end of mooring line to provide a fixation for the mooring line and also for the floater. Typically anchors are designed to take only horizontal loads, such as fluke anchor and plate anchor, while some anchors, like pile anchor, suction anchor, and gravity anchor, can take in addition vertical loads. For large oil and gas platform, winches are arranged at the platform level which allows the length change of individual lines and therefore the heading change of the platform. However, because of the cost issues, floating wind turbines typically do not have winches for mooring system, and mooring lines are fixed at the fairlead. Moreover, connectors are used when combining chain links with steel wire or fiber ropes.

Technical specifications in terms of dimension, weight, ultimate strength, and fatigue strength of mooring line components are provided in DNV (2010). In particular, fatigue design of mooring systems requires in the first step to have a global model for coupled mooring analysis considering both wind and wave conditions. Fatigue S-N (stress-number to failure) curves and very often T-N (tension-number to failure) curves for mooring lines are then used in combination with the global response analysis results for fatigue damage calculation. Fatigue property of chain link and steel wire is well-known, while fatigue tests show a large value and a big scatter of the material slope of the S-N curve for synthetic fiber ropes. Therefore,

Mooring System of Renewable Energy Devices, Fig. 4 Chain links (left), six-strand steel wire ropes (middle), and parallel-subrope fiber ropes (right) (DNV 2010)

fatigue design safety factors are typically chosen very large to reflect the big uncertainties in fatigue property of fiber ropes (DNV 2010).

Mooring System for Floating Wind Turbines, Wave Energy Converters, and Tidal Turbines

In this section, examples of mooring systems for floating renewable energy devices will be given.

Figure 1 shows the three types of floating wind turbines (spar, semi-submersible and TLP) and their mooring systems. In fact, there exist MW-scale floating spar and semi-submersible wind turbine demos, for example, Hywind spar wind turbine (Equinor 2018) and WindFloat semisubmersible wind turbine (PrinciplePower 2018). The third one is a TLP wind turbine with vertical tendons as mooring lines.

The mooring system of the Hywind demo is a taut-line mooring system in combination with clump weights. Near the fairlead of the mooring lines, a delta-line configuration of the mooring system is applied in order to increase the mooring stiffness in yaw so that the natural period of yaw motions is around 8 s. A wind turbine rotor in turbulent wind field may experience unbalanced rotor plane loads, which induces a yaw moment. If the yaw stiffness from the mooring system is too low, there will be a large yaw offset, which may strongly influence the power production of the wind turbine.

The mooring system for the WindFloat prototype is a four-line spread catenary mooring system. Two lines are attached to the column which supports the wind turbine, and the other two lines are for the two remaining columns. The fairleads of the three mooring lines are located at the columns, which is far enough from the central position of the wind turbine tower, to create a large yaw stiffness from the mooring system.

The TLP wind turbine as shown in Fig. 1 has three vertical tendons which are significantly pretensioned due to the excessive buoyancy of the floater as compared to its gravity. As a design requirement, the pretension in each tendon should

be large enough so that it will not go below zero under environmental loads due to wind, waves, and current, which will otherwise induce a transient dynamic effect and therefore large loads in the tendon. Single tendon mooring system is also proposed for one of the floating wind turbine concept, SWAY (2012).

Mooring system for floating wave energy converters depends strongly on the concept and size of wave energy converters. Catenary and single point mooring system is used for large-sized wave energy converters, such as the Wave Dragon overtopping device (2018). Such weather-vane mooring system allows the floater to rotate towards the favorable wave directions. Similar moorings are used for large platforms hosting multiple wave energy converters, for example, oscillating water columns. Most of the pointer absorber wave energy converters are small, and their mooring systems, as shown in Fig. 2, might have a strong interaction effect on the wave-frequency motions of the pointer absorbers and therefore the power production.

For commercial purpose, a big number of wave energy converters should be developed in a farm configuration, similar as those for offshore wind turbines. It has the advantage of smoothing power production based on an appropriate configuration and sharing infrastructures to lower the cost. The simplest way to share the infrastructure is to share the anchors for multiple wave energy converters. In such cases, anchors with vertical capacity are needed. Moreover, the wave energy converters can be interconnected so that the total number of anchors and mooring lines can be minimized to reduce the cost. However, the dynamic behavior of the whole system, including multiple wave energy converters and mooring system, can become quite complicated, and large loads in connecting lines might be induced by adjacent wave energy converters with opposite wave-frequency motions (Gao and Moan 2009).

Most of the ocean and tidal current turbines developed today are bottom-fixed. Some floating tidal turbine plants have been proposed, typically with a spread-moored floating platform which supports one or two turbines. Similar to floating

wind turbines, large mean thrust from tidal turbines will need to be compensated by the mooring forces. In addition, since the tides change directions every 6 h, the tidal turbines are normally designed to work in both directions. As a result, the floater may experience large offset in both directions, and the mooring system should be designed to consider this.

Multidisciplinary Design Optimization (MDO)

Hao Chen

Zhejiang University – Westlake University Joint Training, Zhejiang University, Hangzhou, China

Synonyms

Approximate technology; MDO method; MDO-computing framework; Optimization algorithm; System decomposition; System modeling

Definition

Multidisciplinary design optimization (MDO) is a design methodology for complex engineering systems, which aims to explore the mechanism of synergistic action among subsystems and design complex engineering systems. MDO focuses on the use of optimization algorithms for the design of complex engineering systems which involve a number of subsystems or disciplines. In MDO, the engineering system is divided into different subsystems or disciplines, then the mathematical model of each subsystem is established and the appropriate MDO method is applied to reorganize each subsystem model. Finally, the appropriate optimization algorithm is selected for optimization so as to achieve the optimal design of complex engineering system.

Scientific Fundamentals

Mathematical Model and Basic Concept of MDO Problems

The mathematical model of MDO problems is more complex than that of traditional optimization problems, because the coupling relationship among multiple disciplines or subsystems should be considered in MDO problems. Without loss of generality, for MDO problems that involve a number of disciplines, the mathematical model can be described as follows:

$$\text{Min} : f(x_s, x_i, z)$$

$$\text{S.t.} : g_i \left(x_s, x_i, z_i \left(x_s, x_i, y_{ji} \right) \right) \leq 0 \quad (i = 1, 2, \dots, N; i \neq j)$$

$$h_i \left(x_s, x_i, z_i \left(x_s, x_i, y_{ji} \right) \right) = 0 \quad (i = 1, 2, \dots, N; i \neq j)$$

where f represents optimization objective, g_i and h_i represent inequality constraints and equality constraints of discipline i , respectively. x_s refers to shared design variables, x_i and z_i refer to local design variables and state variables of discipline i , respectively, and y_{ji} is the coupled state variable that discipline j outputs to discipline i . Compared to traditional optimization problems, MDO problems involve more basic concepts. Combined with the MDO problem that involves two disciplines in Fig. 1, some basic concepts involved in MDO problems are introduced as follows:

1. Design variables: Design variables are a group of relatively independent parameters controlled by the designer during the design process. Design variables can be used to represent the basic characteristics of the engineering system. According to the scope of design variables, it can be divided into shared design variables x_s and local design variables x_1, x_2 (see Fig. 1).
2. State variables: State variables are a set of parameters used to represent the response of the engineering system, which can reflect the performance or characteristics of the engineering system. State variables are usually obtained from analysis or calculation models. State variables include system state variables such as the optimization objective, discipline state variables z_1, z_2 , and coupled state variables. The discipline state variables employed as the input to the analysis of another discipline are coupled state variables (i.e., y_{12}, y_{21} shown in Fig. 1).
3. Disciplines: Disciplines, also known as subsystems, represent the basic modules that maintain their relative independence in engineering systems. Different ways of decomposition lead to different disciplinary divisions.
4. Discipline analysis: Taking the design variables of discipline i and the coupled state variables of other disciplines as input, the process

Multidisciplinary Design Optimization (MDO),

Fig. 1 The MDO problem that involves two disciplines

of solving the state equation of discipline i to obtain the output state variable of discipline i is called discipline analysis.

5. System analysis: System analysis is also called multidisciplinary analysis. The system performs repeated iterative calculations with given input variables to coordinate the coupled state variables obtained from the analysis of various disciplines; this process is called system analysis.

Main Research Contents of MDO

Due to the coupling relationship between disciplines, there will be two problems in the multidisciplinary design optimization of complex engineering systems, including organizational complexity and computational cost. A series of technologies and methods on how to solve the two problems of MDO constitutes main research contents of MDO (Sobieszczanski-Sobieski and Haftka 1997), including system decomposition, system modeling, approximate technology, optimization algorithm, MDO method, and MDO computing framework.

System Decomposition

The design of complex engineering system involves high-dimensional nonlinear design variable space, and coupling relationship exists between disciplines; it is very difficult to design and optimize the system directly. Therefore, it

is necessary to use system decomposition technology to change the organizational structure of MDO problems. System decomposition refers to the decomposition of a complex system into several relatively independent subsystems (or disciplines), thus reducing the organizational complexity of the system and shortening the system design cycle. According to the different ways of data transfer within the system after decomposition, system decomposition methods can be divided into two categories:

1. Hierarchical decomposition: For a hierarchical decomposition system, as shown in Fig. 2, data transmission occurs between subsystems of the same level as each other, while there is no information exchange between subsystems of the same level, so parallel analysis and calculation can be carried out. This decomposition method is suitable for multidisciplinary design optimization problems with weak coupling, but difficult to deal with problems with strong coupling.
2. Nonhierarchical decomposition: As shown in Fig. 3, there is no hierarchical relationship in the nonhierarchical decomposition, and data is directly transferred between each subsystem. The decomposition method is suitable for multidisciplinary design optimization problems with strong coupling, which is in line with the practice of complex engineering system design.

Multidisciplinary Design Optimization (MDO),

Fig. 2 Hierarchical decomposition

Multidisciplinary Design Optimization (MDO),
Fig. 3 Nonhierarchical decomposition

After the decomposition of the system, each subsystem can be analyzed and optimized independently, but coordination among subsystems is needed. There are various coordination methods, and consistency constraint (Haftka 1985) is often used to replace the connection between subsystems.

System Modeling

System modeling is realized by using mathematical language to establish the optimization model of the MDO problem and the analysis model of various disciplines. In addition, to clarify the way of data transfer between subsystems, the mathematical model of coupling relationship between subsystems is also needed. System modeling is the basis of multidisciplinary design optimization of complex engineering systems.

Approximate Technology

The approximation technique is the way to build approximate relationships between data based on existing data sets. As shown in Fig. 4, for a given

Multidisciplinary Design Optimization (MDO),
Fig. 4 Approximate technology

input x , there will be a corresponding output y , but the functional relationship between x and y is unknown. Given a large number of inputs ($x_1, x_2, \dots, x_n$), the corresponding output ($y_1, y_2, \dots, y_n$) can be obtained through analysis and calculation. Then, assuming that x and y meet a specific functional relationship (i.e., approximation model), the function relationship can be determined through the existing data set of input and output; this method is called approximation technique.

By replacing the complex discipline analysis process with simple and efficient approximation models, the computational work can be greatly reduced while ensuring a certain accuracy, and the key of approximation technology is to build an appropriate approximation model to replace the corresponding discipline analysis model. Common approximate models include artificial neural network, response surface model, etc. (Sobieszcanski-Sobieski and Haftka 1997).

For the MDO problem of complex engineering system, the calculation amount of a complete multidisciplinary analysis is huge. If the process is coupled into the optimization model for optimization, the calculation amount increases dramatically. In addition, for some subsystems that use

high-precision numerical software as the discipline analysis model, it is difficult to imagine the amount of computing tasks since the high-precision discipline analysis model of the subsystem will be repeatedly called during the whole multidisciplinary design optimization process. So, approximation technique is an essential research content in multidisciplinary design optimization.

Optimization Algorithm

After establishing the optimization model of MDO problem, it is necessary to search the design variable space to get the optimal design scheme. In this process, the optimization algorithm is needed to find the optimal solution.

MDO problem is an optimization problem in essence, and the appropriate optimization algorithm has an important impact on the final solution of the multidisciplinary design optimization problem, so the optimization algorithm is also an important research content of MDO.

Optimization algorithms can be divided into two categories: (1) traditional optimization algorithms (Nocedal and Wright 2006), such as conjugate gradient method, trust-region method, newton method, etc.; and (2) intelligent optimization algorithm (Simon 2013), such as particle swarm optimization algorithm, genetic algorithm, ant colony algorithm, etc.

MDO Method

Multidisciplinary design optimization method is an optimization solution strategy for complex engineering system design. MDO methods reorganize the system through system decomposition and establish the mathematical model of MDO problem by using system modeling technology. The MDO method starts from the engineering system design problem itself and involves several major research contents of MDO, such as system decomposition, system modeling, approximation technology, optimization algorithm, etc. MDO methods can be divided into single-level method and multilevel method. Single-level method only has an optimizer for optimization at the system level, and there is only analysis within each

subsystem (or discipline) without optimization. The multilevel method has an optimizer at the system layer and subsystem layer for optimization.

MDO Computing Framework

The MDO computing framework refers to the computer hardware and software environment that implements the MDO method. The MDO computing framework can integrate and execute the analysis and design of each subsystem, realize the data transfer between systems, and complete the multidisciplinary design optimization of complex engineering systems.

As multidisciplinary design optimization is widely used in the engineering field, the market demand for high-performance MDO computing frameworks increases sharply. A variety of commercial MDO computing frameworks are developed (Salas and Townsend 1998), such as iSIGHT (Engineous Software), ModelCenter (Phoenix), Optimus (LMS Technologies), etc. In recent years, some open source high-performance multidisciplinary design optimization platforms, such as pyMDO (Martins et al. 2009) and OpenMDAO (Gray et al. 2019), have been developed for MDO researchers to learn.

Historical Development

Multidisciplinary design optimization originates from the aircraft design direction in the field of aerospace research (Sobieszczanski-Sobieski and Haftka 1997). In the 1970s, aircraft design methods mostly adopted the traditional serial design method; this method has many drawbacks, such as ignoring the coupling relationship between disciplines, low efficiency, long design cycle, and high cost.

In order to overcome the drawbacks of traditional design methods, multidisciplinary design optimization was proposed as a new design methodology in the 1980s. Sobieszczanski-sobieski (1982) proposed the concept of multidisciplinary design optimization for the first time in a research paper on structural optimization. Since it was

proposed, MDO has received great attention from academia and industry. In 1986, AIAA, NASA, OAI, and USAF in the United States jointly organized the first symposium on “Multidisciplinary Analysis and Optimization.” Since then, the conference has been held every 2 years and has become a leading international academic conference in the field of MDO.

In order to promote the research and development of MDO, Sobieszczanski-Sobieski (1995) presented a review about MDO; this paper attempts to define the MDO as a new field of research endeavor and as an aid in the design of engineering systems. The Multidisciplinary Design Optimization Branch (MDOB), established by NASA’s Langley Research Center, proposed a test suite in 1996 to measure the performance of MDO methods (Padula et al. 1996). With the promotion of these scientific research institutions, the theoretical research of MDO entered the stage of rapid development in the 1990s, among which the multidisciplinary design optimization method is the core content and frontier of the theoretical research of MDO. In this stage, many classical MDO methods are put forward one after another, including multidisciplinary feasible method (MDF) (Cramer et al. 1994), all-at-once method (AAO) (Cramer et al. 1994), individual disciplinary feasible method (IDF) (Cramer et al. 1994), concurrent subspace optimization method (CSSO) (Sobieszczanski-Sobieski 1988), collaborative optimization method (CO) (Kroo et al. 1994), and bilevel-integrated system synthesis method (BLISS) (Sobieszczanski-Sobieski et al. 2000), in which MDF, AAO, and IDF belong to single-level MDO methods, and CSSO, CO, and BLISS belong to multilevel MDO methods.

In the twenty-first century, the theoretical research of MDO focuses on the improvement of the classical MDO method. Sobieszczanski-Sobieski et al. (2003) reconstructed the system optimization problem on the basis of BLISS and proposed the BLISS-2000 method, in which the information exchange between the system and the subsystem is realized by the approximate model of the subsystem optimization, and the objective function of the subsystem optimization is

represented by the weighted sum of the state variables of the subsystem. Based on the MDF method, Chittick and Martins (2009) proposed a new distributed MDF method, which is called Asymmetric Subspace Optimization (ASO). Aiming at the problem that the coupling variables are difficult to be resolved, Li et al. (2016) proposed a standard for determining the coupling variables, combined it with CO method, and proposed an improved collaborative optimization (ICO) method.

Key Applications

After nearly 40 years of rapid development, the multidisciplinary design optimization theory is becoming mature and gradually moves from the theoretical research stage to the engineering practical application stage. In addition to the successful application in the aerospace field, such as aircraft design optimization (Braun et al. 1996; Jun et al. 2006; Park et al. 2009; Setayandeh and Babaei 2020), multidisciplinary design optimization technology is also widely applied in the field of ship and ocean engineering. Wang et al. (2007) applied the concurrent subspace design method (CSD) to the shape design of a certain AUV. Luo and Lyu (2015) applied the collaborative optimization method to the hydrodynamic performance optimization of underwater unmanned vehicle (UUV). Liu et al. (2017) carried out the research on the multiple objective multidisciplinary design optimization of heavier-than-water underwater vehicle using CFD and approximation model. Bidoki et al. (2018) proposed the PSO-MDF method, by combining the particle swarm optimization algorithm and MDF method, and applied it to the multidisciplinary design optimization of an autonomous underwater vehicle (AUV). Chen et al. (2018) divided the design of AUV into three subdisciplines, including hydrodynamic discipline, control discipline, and energy and weight distribution discipline, and then applied the MDF method to the overall conceptual design optimization of AUV. Bidoki et al. (2019) presented an improved multidisciplinary design optimization methodology for conceptual design

of an autonomous underwater vehicle in both engineering and tactic aspects under uncertainty.

Navigation Buoy

Wanan Sheng
SW MARE Marine Technology and Consultation,
Cork, Ireland

Definition

A Navigation Buoy is a special floating buoy (or maybe fixed in occasional cases) that are set on waters for enhancing safety of sea activities

by providing lights and/or marks and other relevant information. For instance, it is of vital importance for marine traffic to obtain correct LOPs. It is also called Aids to Navigation buoy (AtoN buoy). Figure 1 shows a typical navigation buoy.

Scientific Fundamentals

The International Association of Marine Aids to Navigation and Lighthouse Authorities (IALA, previously known as International Association of Lighthouse Authorities (<http://www.iala-aism.org/>)) is an Intergovernmental organization founded in 1957 to collect and provide nautical expertise and advice. Since 1973, the principal work has been implemented as the IALA Maritime Buoyage System. This rationalized system was introduced as a result of two accidents in the Dover Straits in 1971 when the *Brandenburg* hit the wreck of the *Texaco Caribbean* off Folkestone; and shortly later the *Niki* struck the *Texaco Caribbean*. The combined loss of lives in these two accidents was 51 persons. As a result of the accidents, a new system was essentially established to replace some 30 dissimilar buoyage systems in use throughout the world with two internationally standardized systems.

Although the international agreement of 1982 implementing a harmonized buoyage system is a major achievement for the IALA Organization, through its committees carried out a lot of works in other directions resulting in innovating

Navigation Buoy, Fig. 1 Typical navigation buoy with a light and a chart symbol on top. (Adopted from <https://www.ybw.com/features/navigation-essential-buoys-marks-8611>)

techniques being adopted all over the work, such as the AIS (Automatic Identification System), DGNSS (Differential Global Navigation System), and many others.

Key Applications

Regardless of which system you use, there are six types of navigational marks: lateral; cardinal; safe water; isolated danger; emergency wreck, and special. Now IALA is known for the IALA Maritime Buoyage Systems or sea mark systems that are used in the pilotage of vessels at sea (following information adopted from <https://www.irishlights.ie/>):

1. Lateral Marks

Lateral Marks are generally used for well-defined channels (Fig. 2). They indicate the port and starboard sides of the route to be followed. They are positioned in accordance with a Conventional Direction of Buoyage.

Navigation Buoy, Fig. 2 Lateral marks

Navigation Buoy, Fig. 3 Cardinal marks

Lateral Marks in region A use red to denote port and green to denote starboard **when returning from sea**. In region B, the reverse applies.

2. Cardinal Marks

A Cardinal mark is named after the quadrant in which it is placed. The name of a Cardinal mark indicates that it should be passed to the named side of the mark. The mariner will be safe if they pass north of a North mark (“N”),

Navigation Buoy, Fig. 4 Safe water mark

Navigation Buoy, Fig. 5 Isolated danger marks

south of a South mark (“S”), east of an East mark (“E”) and west of a West mark (“W”) in Fig. 3.

A Cardinal mark may be used, for example, to:

- Indicate that the deepest water in that area is on the named side of the mark.
- Indicate the safe side on which to pass a danger.
- Draw attention to a feature in a channel such as a bend, a junction, a bifurcation, or the end of a shoal.

Cardinal Marks are also used for permanent wreck marking whereby North, East, South, and West Cardinal buoys are placed around the wreck. In the case of a new wreck, any

Navigation Buoy, Fig. 6 Emergency wreck marking buoy

Navigation Buoy, Fig. 7 Special marks

one of the Cardinal buoys may be duplicated and fixed with a Radar Beacon (racon).

3. Safe Water Marks

Safe water marks serve to indicate that there is navigable water around the mark (Fig. 4). These include centre line marks and mid-channel marks. They may also be used to indicate channel entrance, port or estuary approaches, or landfall.

4. Isolated Danger Marks

Isolated danger marks are used to mark small, isolated dangers with navigable water

Navigation Buoy,
Fig. 8 Symbols and abbreviations for light characteristics

Description	Characteristic	Chart Abbreviation
Alternating		Alt. R.W.G.
Fixed		F.
Flashing		Fl.
Group flashing		Gp Fl.(2)
Occulting		Occ.
Group occulting		Gp Occ(3)
Quick flashing		Qk.Fl.
Very quick flashing		V.Qk.Fl.
Isophase		Iso.
Morse		Mo.(letter)

around the buoy. Typically used to mark hazards such as an underwater shoal or rock. They are red and black in color (Fig. 5).

5. Emergency Wreck Marking Buoy

These buoys mark new wrecks clearly and unambiguously. Used as a temporary response, they are colored in an equal number of blue and yellow vertical stripes and fitted with an alternating blue and yellow flashing light (Fig. 6).

6. Special Marks

Special marks are used to indicate a special area or feature whose nature may be apparent from reference to a chart or other nautical publication. Special marks are yellow. They may carry a yellow “X” top-mark and any light used is also yellow (Fig. 7). Uses of special marks include:

- Ocean Data Acquisition Systems (ODAS) marks
- Traffic separation marks where use of conventional channel marking may cause confusion
- Spoil ground marks
- Military exercise zone marks
- Cable or pipeline marks
- Recreation zone marks
- Boundaries of anchorage areas
- Structures such as offshore renewable energy installations
- Aquaculture

In addition, each type of mark has a distinctive color, shape, and possibly a characteristic light (see Fig. 8).

Navigation of Polar Vessel

Jianhua Cheng and Jing Cai
College of Automation, Harbin Engineering University, Harbin, China

Introduction

In terms of geodynamics, meteorology, hydrology, and geography, the polar regions are too unique to lead to the normality of the conventional navigation methods commonly used in the low-medium latitude. Therefore, it is impossible to reach the predetermined destination safely, accurately, and effectively for the carries and the individuals. With the further exploration of polar natural resources, the researches corresponding to the polar navigating methods have already been becoming a critically significant part of safe voyage in polar regions. Firstly, the article defines the polar region and polar navigation. Then, the challenges easily encountered by conventional navigation methods are

analyzed. Finally, the application status of existing methods is introduced in detail.

Introduction of Polar Navigation

Individuals and carriers, such as vessels, aircrafts, spacecrafts, terrestrial vehicles, etc., utilize the electric, magnetic, acoustic, optical, mechanical, and other methods in the polar regions. And, the target is to locate the moving body by measuring the corresponding kinematic parameters and then to guide it from one point to the destination along the predetermined route safely, accurately, and economically, which is called polar navigation.

Baidu Baike proposes the definition of the polar navigation: navigation in the Antarctic and the Arctic. However, the definition of polar regions corresponding to navigation differs from it defined by the geographic circle of the Antarctic and the Arctic. Hitherto, these two definitions have not agreed with each other yet. In Advisory Circular (issued on June 13, 2018), Federal Aviation Administration (FAA) defines the polar region for aviation navigation. 78°N and more is the Arctic region; 60°S and more is the Antarctic region. This is the most authoritative definition of polar regions.

Nowadays, the ice sheet in the Arctic and the Antarctic is melting rapidly along with global warming. With the background of economic growth and regional integration, polar regions weight heavily on aspects of strategy, economy, science, environmental protection, marine channel, natural resource, etc. With the geospatial advantages in military, resource exploration, and marine transportation, the polar area significantly values in sustainable economic development and national security. Therefore, the polar regions place the pivotal position in marine exploration and probe. However, due to the special geographic location and natural environment in the polar regions, the navigation methods, such as radio, satellite, geomagnetic, inertial, and celestial navigation, cannot work properly, which are commonly used in the low-medium latitude. For example, polar regions are near the South Pole

and the North Pole of the earth. Its unique location causes the convergence of geographic meridians at the geographic poles. Because of the acute convergence of meridian, it is significantly hard to define the heading, relative to the meridian. Moreover, all directions are even toward the south, overhead the North Pole. That, mentioned above, directly restricts the application of the traditional mechanism of the inertial navigation system in the polar regions. The geomagnetic poles are also located in the Arctic and the Antarctic. Its characteristics are the weak horizontal component of the geomagnetic field and the large change of magnetic variation over a large part of the polar regions. Then, it leads to the incapability of the magnetic compass to show reliable directions. Another factor is the abominable and capricious polar natural environment, such as geomagnetic storm, polar day and night, etc., which totally differs from the low-medium latitude. The working characteristic of navigation systems will change and even fail to perform properly. For instance, in polar regions, the ionospheric scintillation frequently occurs. The magnetic storm and solar flare periodically happen, directly triggering the cutoff effect. It is prone to affect the positioning capability of satellite navigation. Radio navigation requires an arrangement of navigation stations on the ground. However, because of polar landforms and climate conditions, its arrangement is restricted. Thereby, applications of radio navigation are limited as well. Besides, wind and low visibility of polar regions, as the major meteorological factors, limit the implementation of landmark navigation technique, visual navigation technique, and celestial navigation technique (Maclure 1949; Qi-Ju et al. 2014).

Navigation technology has always been a critical warranty for the safe and economic navigation of civil vehicles, while the development of polar navigation technology strongly supports the feasibility of polar navigation. In August 21, 1914, Y.I.Nagurskiy, the Russian Royal Navy Captain, flew to the high latitude for the first time. In 1945, Aries I completed the mission of aviation toward the North Pole. So far, western developed countries, especially in Europe and

America, and Russia already have a much more perfect strategy to aviate in the polar regions and even through at the poles. In 2001, it indicates that the polar navigation technology has already matured in Europe and America, when Boeing opened a polar commercial airline connecting North America and Asia. The latest models of large active commercial aircrafts, belonging to Boeing and Airbus, are able to achieve global flight. IRS (inertial reference system) is equipped as the main navigation system when flying over the polar regions. In addition, attribute to the Russian research about the polar navigation, its polar navigation technology grows more and more maturely. Due to the huge potential of polar routes, 2001 China Eastern Airlines 2350 Airbus A340 aircraft, Boeing 777-21BER B-2055 aircraft of China Southern Airlines was trialed for the polar flight. At present, Chinese scientific research ship "Xue Long" has completed eight times scientific research missions in the Arctic. Obviously, during the polar region navigating, polar navigation technology plays a critically important role. It can not only determine the location of the vehicle itself and its destination but also reduce the frequency of the accident occurrence.

Polar Navigation Methods

Along with the improvements and developments of polar navigation until now, the common navigation methods include:

Inertial Navigation

The earliest application of the polar inertial navigation could date back to 1958. American "Nautilus" nuclear submarine, equipped with N6A inertial navigation system, sailed underwater for 21 days and succeed to cross the North Pole. Its voyage is 8146 nautical miles, while its positioning error is only 20 nautical miles during the whole sailing (Lyon 1984). Compared with traditional navigation methods, like electro-magnetic navigation technique, and traditional navigation methods, the polar inertial navigation technology has the advantage of stable

performances in the harsh polar environment. And it is proved to be an optimal strategy to sail toward and in the polar regions. The inertial navigation systems can be arranged by different mechanisms. The mechanism propagated in the east-north-up frame is easy to understand and clear to physically expressed. However, its shortcomings in the polar regions are to hardly apply torques on azimuth gyro, to overflow in the system computer calculation, and to amplify errors of positioning parameters. To solve its problems, the inertial navigation mechanism proposed in wander angle frame can avoid the overflow caused by convergence of polar meridians. This mechanism was adopted by the early LN-51 aviation navigation system (DelCore and Nascro 1986). However, as for the wander angle introduced purposely, its error is also amplified with the increase of the latitude. Meanwhile, the position extracted from the cosine direction matrix (CDM) is almost singular, when it is very close to or just at the pole. Thus, the system performs badly. For solving problems of the wander angle frame in the polar regions, the mechanism of the earth-centered earth-fixed coordinate system (ECEF), grid coordinate system (Ignagni 1972), and transverse coordinate system (Dyer 1971) can be adopted reasonably. They are all with abilities of global flight, further to achieve polar navigating. In 1958, "Skate" nuclear submarine and "Sargo" just utilized the grid inertial navigation system and completed polar navigating missions. The MAPS inertial navigation device of Honeywell is used by the National Defense Department of Canada for autonomous navigation in the high latitude (84°N). The Russian Vega-M inertial compass system is able to guarantee the medium-precision output of attitude and heading between 85°S and 85°N. The icebreaker, equipped with the Vega-M system, arrived at the area of 89°N in 2003. It is proved that, when the operation exceeds the range of the system, the navigation errors will surge obviously (John et al. 2003).

Satellite Navigation

At present, four major global satellite navigation systems are GPS of the United States, GLONASS

of Russia, Galileo of Europe, and BDS of China. In the polar regions, the arrangement of the satellite navigation system constellations directly affects the positioning accuracy. BDS is mainly a high-orbit satellite, mainly above the Asia-Pacific. The average number of satellites over the medium-high latitude is about two, less than GPS, Galileo, and GLONASS. Its geometric arrangement is poor, and then positioning precision descends sharply. The number of visible satellites of GPS changes little with the latitude and longitude, all about 8–10 satellites. So is in the polar regions. The number of visible satellites of Galileo in the polar regions is always more than four. Moreover, with the completion of the full constellation in 2018, the number of its visible satellites in the high latitude will be more than that of GPS. Because Russia is located at the high-latitude area, the GLONASS is designed to place more satellites in the high-latitude region. So the number of visible satellites in the polar regions is the largest. Besides, its satellite inclination is the highest, which results in a better performance of constellation geometry in high latitude. Although more visible satellites are distributed in polar regions with the comparison of the low-medium latitude, most satellite's elevation angle is relatively low. In addition to constellation distribution, the tropospheric delay is another key factor for satellite positioning. The related research confirms that the tropospheric delay influences more on the observation of satellites of a low elevation angle. The polar ionosphere scintillation occurs frequently, while the daily fluctuation of the total electron content (TEC) is more fierce than low-medium latitude. Besides, due to the uniqueness of polar regions, it is hard to use satellite-based or ground-based augmentation systems to modify the positioning accuracy. For example, for satellite-based systems like EGNOS and WWAS, the polar regions cannot be covered by the geostationary earth orbit (GEO) satellites, only seen in part of regions and time. For ground-based augmentation systems, there have been a few observation stations in polar regions. Meanwhile, the harsh environment condition makes the establishment of long-time stations difficult, like lack of support of

sustainable energy and chain of real-time communication, etc. (Yuanxi and Junyi 2016). Therefore, the positioning performance of the satellite navigation system in the polar area is at subpar levels.

Celestial Navigation

Same as the polar inertial navigation technology, the polar celestial navigation technology is also autonomous. The polar celestial navigation technique uses the star sensor to track the relative celestial bodies' position in space, in which it is an accurate and passive system. Then, the navigation computer can calculate the navigation information through observed parameters. The advantage is that it is not influenced by the magnetic field deception jamming and has a good performance of concealment. Thus, since the development of the star sensor in the 1990s, it has been widely used in the military and civil (van Bezooijen 1994) and has increasingly played a key role in polar navigation as well. Even under some specific conditions, it is the only method that can be relied on. However, the special sailing conditions in the polar regions restrict the operation of polar celestial navigation technology to a certain extent. Especially the polar navigators might be caught in the long twilight which may last for several days, when neither sun nor stars are available. Meanwhile, because the update rate of the celestial navigation system is low, it lacks the capability of the provision of real-time navigation information. Thus, it is usually an adding method to correct accumulative errors of the inertial navigation system for autonomous, high-precision, and long-time navigation. It has been confirmed that the careful dead reckoning and hourly celestial bodies' observations are sufficient for reasonably accurate navigation (Molett 1954). Taking the American air force as an example, it has been contributing to this kind of research since the 1950s, such as the NAS-26 inertial/celestial integrated navigation system in the 1980s and the SAIN strapdown inertial/celestial navigation system in the 1990s. They are all the typical airborne inertial/celestial integrated navigation products (Ming 2019).

Underwater Acoustic Navigation

Polar underwater acoustic navigation technology helps increase the transparency of underwater space and enhance the survival ability of underwater vehicles. Research in navigation and localization algorithms, along with advances in acoustic positioning and seafloor relative Doppler velocity log (DVL) measurements, has significantly advanced the state of the art over the past two decades. However, operating in the polar regions presents unique challenges – first and foremost that surface roughness interacts with wind and current due to the polar sea ice, which tends to form underwater noise easily. The noise will extremely limit the performance of the sonar. Moreover, polar seafloor conditions are more unpredictable and severe. Under the unknown underwater condition, it is difficult for acoustic signal beacons to be installed and arranged all over the seafloor. By this very existence, vehicle and ship are hard to access to the free surface and, therefore, require fundamental changes in the methods of operation. At the same time, the navigation methodology employed must be modified as well (McFarland et al. 2015). In order to extend the voyage, Russia, America, and other countries are all active to develop innovative underwater acoustic navigation systems to adapt to the special underwater sailing circumstance in the polar regions. For example, Russia actively explores an innovative underwater acoustic navigation system, composed of the GLONASS navigation system, sonar buoy, and unmanned underwater vehicles. And, the system is located on the continental shelf of the Arctic Ocean of Russia.

Integrated Navigation

In order to further improve the accuracy and reliability of navigation, the vehicle can adopt a combined working mode as the integrated navigation, which means that it takes one of the navigation methods as the dominant with the aid of various navigation systems. Thus, the integrated navigation system can suppress respectively systematic errors contained in each system to achieve accurate positioning and navigating. Considering the mature technology of the integrated navigation of the foreign underwater

vehicles, the integrated navigation system is mainly the strapdown inertial navigation system plus Doppler sonar. Its positioning accuracy can reach 0.01% of its voyage. For example, with the aid of the same Doppler velocity log (DVL), one underwater vessel of the Bluefin Robotics Company of the United States carries the laser inertial navigation system, while another takes optical fiber inertial navigation system for the sea trial. And its results demonstrate that both two systems have relatively high precision (Tal et al. 2017). Because the performance of celestial navigation will be interrupted by the polar environment, it always collaborates with the inertial navigation system. For instance, the LN-120G inertial/celestial integrated navigation system of the United States can globally navigate. It is with capabilities of fully autonomous, high-precision, and long-time navigation. Its positioning precision even reaches 0.5 nautical miles per 18 h (<https://www.northropgrumman.com/Capabilities/LN120GStellarInertialNavigationSystem/Pages/default.aspx>). Until now, China has been also active to develop the integrated navigation system to adapt to polar navigation. For example, “Yong Sheng” owned by China Ocean Shipping (Group) Company (COSCO) first voyaged successfully through the Arctic in 2013. The GPS compass equipped on the ship is the high-precision integrated navigation system. The system is improved by the fusion of dual antenna azimuth solution technology of GPS and fiber optic gyroscope technology.

Definition

Biofouling, i.e., marine biological fouling, corresponds to the accumulation of microorganisms, plants, and aquatic animals on artificial surfaces immersed in seawater. Biofouling is an ocean phenomenon and an important scientific and technical term to understand what happens to artificial surfaces in seawater while exploiting ocean resources in terms of the following in aquaculture and mariculture: the biofouling community, fouling community, and foulant communities; the foulant, fouler, and fouling organisms; pens, artificial structures enclosed on all sides with the bottom formed by the sea bed, or cages, artificial

structures enclosing all submerged surfaces; the stocking density, the amount of fish in the cage or the total number of fish inside; and the mesh occlusion and mesh plugging abundance of fouling organisms.

Scientific Fundamentals

The structure, composition, and large surface areas of netting materials, especially multifilament meshes, are highly suitable for the colonization and development of biofouling (Ashraf et al. 2017). Biofouling often develops rapidly because the seawater surrounding aquaculture operations is enriched by inorganic and organic wastes (food residues, feces, and excretory material) generated by high-density fish populations (Navarro et al. 2008; Sanderson et al. 2008). The increases in carbon, nitrogen and phosphorus in the seawater surrounding mariculture farms facilitate the growth of annual filamentous algae (Ruokolahti 1988). The rapid growth of fouling in eutrophic seawater leads to the complete blockage of the netting mesh within 2–3 months (Neori et al. 2004). The biofouling of fish-cage netting can lead to significant operational problems in aquaculture. Mesh plugging and the resulting restriction on water exchange adversely influence the health of fishes owing to the reduction in dissolved oxygen (DO) and the accumulation of metabolic ammonia. Fouling is an additional concern because it significantly decreases cage flotation, increases structural fatigue and cage deformation, and may act as a reservoir for pathogens (Amaraa et al. 2018). The impacts of fouling vary dramatically depending on the season and location and are also influenced by the farming methods and practices.

The fouling of mariculture structures differs from that of many other marine industries, in particular, marine transport, in terms of the surface characteristics; specifically, the surface is rough, and consequently, the surface area is large (Bixler and Bhushan 2015). Moreover, the fouling of mariculture structures is not subject to the high water velocities and shear forces associated with ship hulls or the internal surfaces of pipes. Early

studies on the fouling on mariculture netting showed that the netting material and mesh size significantly affected the fouling rate, mesh occlusion, and density and abundance of fouling species (Rothwell and Nash 1977). According to these data and observations of mesh deterioration, materials were rated for their suitability in the construction and maintenance of fish cages. More recently, the effects of the net angle and microfouling development on multifilament meshes (Corner et al. 2007) were investigated. However, due to the importance of the aquaculture industry in global economic development, the number of studies on the impact of marine biofouling in all forms of aquaculture is limited and often disparate and sparse.

Development of Biofouling in Mariculture

In intensive commercial mariculture, multifilament netting bags or cages suspended from a floating frame are usually utilized. In particular, high standards of water quality must be maintained through water exchange, which depends on the speed and direction of water flow, which is affected by the salinity, temperature, and topography of the site (Beveridge 2004). The key nature of water exchange renders the influence of biofouling critical on all forms of aquaculture, especially cage-based aquaculture. The main effect of biofouling on cages is to restrict the water current, the effect of which increases as the biofouling communities develop from a biofilm to a complex three-dimensional climax community dominated by sessile invertebrates.

The development and composition of fouling communities on fish cages has been investigated for many types of mariculture (Cronin et al. 1999; Greene and Grizzle 2007). Multifilament mesh materials are generally regarded ideal fouling surfaces, and the succession of organisms attached to aquaculture networks has been specifically evaluated (Svane et al. 2006). Even after immersion for a short period of time, for instance, less than a month, macroalgae are usually found to be the most serious type of foulants on cages (Hodson

Net Structures: Biofouling and Antifouling,

Fig. 1 Hydroids fouling a testing net in Zhoushan during late summer. Hydroids are common and problematic fouling organisms, which are hard to dislodge and regenerate rapidly. These organisms reduce the flow and oxygen levels within cages, and constant management is required to prevent their impact on the growth and survival of cultured fishes in the cage. (Photograph by Hailong Zhang)

and Burke 1994). In contrast, several other marine organisms, such as bivalves, ascidians, and hydroids (Fig. 1), may be the predominant foulants on cages after immersion for longer periods, although these organisms may also cause serious fouling problems even in a brief period, especially during periods of high larval settlement (Greene and Grizzle 2007).

Variation in Biofouling Between Sites: On a large scale, considerable differences exist in the biofouling between sites, for example, between temperate and tropical waters (> 1000 km). However, spatial variation also occurs on a smaller scale (< 100 km). The differences in sites may represent variations in the environmental conditions, such as differences in the seawater quality, salinity and temperature, as well as differences in the abundance of larval stages (Santhanam et al. 1983). For instance, the fouling communities on polyethylene netting differ between cages immersed in brackish and marine waters. Cages in brackish water (24.5–33.8%) are usually colonized by the algal genera *Enteromorpha* and *Ectocarpus*. However, the cages in marine conditions (36%) are usually colonized by a more diverse community, including bivalves, sea anemones, solitary and colonial ascidians, algae (*Caulerpa* spp., *Codium*

spp., and *Gracilaria* spp.), amphipods, barnacles, and polychaetes (Santhanam et al. 1983).

The Variation in Biofouling Within Sites is mainly driven by the effectiveness and availability of light and water flow, which are related to the depth and orientation of the cage (Cronin et al. 1999). The differences in the photosynthetic biomass between the cage sides are detectable only near the surface where light intensity variation is most pronounced; for instance, the significant fouling changes that occur at a depth of 0.5 m become nonsignificant at a depth of 2.0 m. Overall, the fouling mass decreases significantly with increasing depth.

The direction of immersed surfaces affects the development of fouling organisms, and a significant difference exists between vertical and horizontal substrates. This aspect was demonstrated in a comparison of vertical and horizontal net panels. The vertical panels fouled more rapidly, developed a greater fouling biomass, and exhibited an increased abundance of compound ascidians and tubeworms. However, barnacles and oysters were found to be more abundant on the horizontal frame (Cheah and Chua 1983). The increase in biomass on the vertical panel was believed to reflect a greater interception of horizontally moving planktonic larvae, which increased the larval settlement. However, an increase in collisions with suspended material increases the nutrition of filter-feeding organisms. Compared with the vertical surface, communities on the horizontal surface are more prone to siltation and predation, and vertical or stacked species are favored. However, on vertical surfaces, in which critical competition for space occurs and the predation pressure is less, colonial growth is more effective (Harris and Irons 1982). In addition, the relative abundance of individual bivalves was observed at the bottom of a cage, and more individuals were observed to grow on the outer than on the inner surfaces of a cage (Lee et al. 1985).

Netting and Biofouling

Because the waters around mariculture sites are rich in organic and inorganic wastes produced by

high-density fish populations, biofouling usually occurs extremely rapidly. The fouling of mariculture structures is different from that of structures in many other marine industries, especially marine transportation, because of the rough surface and high surface area. Moreover, such fouling is unaffected by the high flow velocities and shear forces associated with the surface of ship hulls and the inner surface of pipes. Early studies on the surface fouling of mariculture cages showed that cage materials and mesh sizes considerably influence the fouling rate, mesh occlusion, and density and abundance of fouling organisms (Rothwell and Nash 1977). Based on these data and the observed mesh deterioration, materials are evaluated to determine their suitability for the construction and maintenance of fish cages. Recently, the influences of the mesh angle and development of microfouling on multifilament mesh have also been investigated (Corner et al. 2007).

Influence of the Mesh Size of a Cage

In commercial fish farming, a variety of mesh sizes are adopted, ranging from 12–40 mm, 60–90 mm, and 100–150 mm for salmon cages, bluefin tuna cages, and predator fences, respectively. Larger grids usually have thicker gauges; however, a smaller mesh size corresponds to a larger surface area per square meter. Therefore, smaller grids usually incur more fouling organisms and total biomass. In general, the fouling rate, fouling quality, species diversity, and species richness increase as the grid size decreases (Cheah and Chua 1983). Consequently, to maintain acceptable water exchange, small grid nets must be cleaned more frequently than larger nets. High sediment loading does not require an excellent substrate for the settlement and growth of foulants because the accumulation of silt makes the surface of the multifilament mesh rougher. Thus, the grid size and total surface area are believed to interact and influence the development of biofouling.

Influence of the Mesh Structure

The distribution and type of the initial fouling process were reported to be influenced by the micromorphology of the multifilament mesh

(Hodson and Burke 1994). The cylindrical shape of the grid strip resulted in different light intensities on the upper and lower surfaces of the horizontal submerged grid strip. Therefore, a community of phototrophic organisms (such as diatoms) formed on the upper surface of the horizontal strip, and a heterotrophic protozoan community developed on the lower surface.

The large crevices and many filaments on the surface of netting rope are likely to contribute to the attachment of fouling organisms, either because of the entrapment of suspended matter or because several larvae of fouling invertebrates and spores of common fouling organisms preferentially settle in small depressions. For many organisms, a preferred settlement size exists, which may affect the community composition of micro- (Scardino et al. 2006) and macrofoulants (Scardino et al. 2008).

The three-dimensional structure of a net mesh directly affects the development of fouling on netting. The occurrence of biofouling attachment has been noted to be preferential at grid intersections (Tseng and Yuen 1979); for instance, researchers observed the appearance of a large aggregation of mussels at the intersection and the presence of bryophytes, barnacles, and green algae mainly at the intersection. This preferential attachment is presumably due to the larger surface area and turbulence changes in certain sea areas.

Influence of the Mesh Material

A number of suitable materials have been employed for the construction of fish cages. These materials have different degrees of antifouling capabilities. In this respect, some studies have proven the relative capacity of many types of netting: multifilament polymer nets, extruded polymer meshes, metallic hardware cloths, and extruded metal meshes.

After examining ten mesh types, polymer-fiber nets and galvanized meshes were found to be the most and least vulnerable to marine fouling, respectively. After 4 months of immersion, the polymer fiber mesh was completely blocked by the growth of marine organisms (Fig. 2), and the weight of the test panel (0.4 m²) increased from 5.5 kg (clean) to more than 15.5 kg. In contrast, a

Net Structures: Biofouling and Antifouling, Fig. 2 Settlement of marine organisms on the small mesh net. As a monospecific group, hydroids usually breed rapidly, increasing the weight of nets, and can easily block the water flow through nets of small mesh sizes. (Photograph by Hailong Zhang)

reasonable flow of water passed through the galvanized material mesh, and the weight of the panel increased from approximately 7 kg to 9 kg. Furthermore, nylon and polyethylene meshes were found to foul at a significantly greater rate than metal meshes. In addition, the polyethylene mesh and galvanized mesh exhibited the greatest and least fouling, respectively, after 5 months (Rothwell and Nash 1977).

In addition, the fouling community composition differed among various grid types. First, algae propagated on most nets but became most abundant on nylon nets and nets with ineffective antifouling paints. All the panels were rich in serpulid tubeworms; however, these organisms were not widely observed on extruded polymer mesh- and PVC-coated chain links, on which barnacles were abundant after 5 months (Rothwell and Nash 1977).

According to this discussion, the material, mesh structure, and mesh size of cages have important impacts on the biofouling rate, mesh blockage, and fouling biological density and quantity. Fouling communities in cages are usually developed and characterized by a large quantity of biomass. For example, the species composition of a biofouling community immersed in seawater for 4 months is almost the

same as that immersed for 2 months, although the weight of the former will be doubled (Cheah and Chua 1979). Nevertheless, large amounts of silt are often deposited and associated with those biofouling communities. For example, one study reported that 58% of the total fouling biomass with an area of 4.5 kg/m^2 is silt (Lee et al. 1985).

Impact of Biofouling on Mariculture

Factors Limiting Water Exchange

The main concerns pertaining to fishnet cage fouling relate to the mesh blockage and change in the water quality due to the limitation on the water flow. The water exchange inside and outside the cage is influenced by the external velocity (Edwards and Edleston 1976) and the angle between the mesh and flow (Gularte and Huguenin 1984). The differences in transmission measurements may be due to the methods used to quantify the flow, the stocking density of the cages, and the circulating flow generated by the fish. The transmission of a clean net is related to the mesh size and usually varies between 50% and 80%. Due to the biofouling of the mesh and the grouping of the cages, the transmission decreases significantly. After 52 days, 80 days, and 120 days in the ocean, the transmission rate (57.5%) of a clean 13 mm mesh decreased to 23.4%, 18.7%, and 13.1%, respectively, with the corresponding fouling biomass weights being 1.85 kg/m^2 , 2.84 kg/m^2 , and 4.98 kg/m^2 (Wee 1979).

When three 9 mm mesh cages were placed parallel to the flow, the flow decreased in a serial manner, and the transmission rate decreased from 70% for the first cage to 35% and 18% for the second and third cages, respectively (Inoue 1972). As the cages were arranged in a series and the netting became fouled by marine organisms, these two effects dramatically reduced the exchange of water (Aarsnes et al. 1990). Hence, grouped cages are suggested to be oriented perpendicular to the current, with no more than two or three cages in a series being placed parallel to the current (Beveridge 2004).

In the fish farming industry, a common practice is to increase the size of the net pen and place large

nets in the sea throughout the production cycle (Sunde et al. 2003). In this scenario, the effects of biofouling on the water exchange and net deformation are expected to become more severe because larger cages and nets have smaller surface area to volume ratios than smaller nets, resulting in lower water exchange rates (Lader et al. 2008).

Factors Limiting Water Quality

Water exchange is essential to replenish dissolved oxygen and remove excess feed and waste materials to maintain the water quality. Many studies have demonstrated a decrease in the oxygen concentration from the outside to the inside of cages and clarified the relationship between the oxygen reduction and short-term water exchange (Wee 1979). In addition, an increased stocking density increases the oxygen consumption inside cages (Kadowaki et al. 1978). Therefore, combined with low current flow and significant mesh blockage and a high density of fish, dissolved oxygen may rapidly decrease to critical levels (Edwards and Edelston 1976).

Kennedy et al. (1977) reported the mortality of fish due to anoxia in severely fouled cages, in which the dissolved oxygen (DO) concentration was less than 4.0 mg/L. Low water exchange was found to directly cause this low DO concentration in the cages. After installing a clean net, the concentration of DO increased to 8.25 mg/L. For salmon aquaculture, the oxygen concentration is recommended to be greater than 7 mg/L; notably, a concentration less than 5 mg/L will have a negative impact on the growth and respiration of fish, and a concentration less than 2 mg/L will lead to mortality (Boyd 1982).

Many factors contribute to the total supply and consumption of DO in the cage (Silvert 1994; Cronin 1995). In particular, oxygen supply occurs primarily through water exchange but also through the photosynthesis of foulant communities and atmospheric diffusion. Although oxygen is mainly consumed by fish, to some extent, it is also consumed by the biochemical oxygen demand of the immediate environment and fouling communities. The maximum stocking density of fish depends almost completely on the exchange of water and can be calculated

according to oxygen consumption and the oxygen supply rate. Although the oxygen levels in cages are mainly controlled by the water exchange, the production or consumption of oxygen by the fouling community can affect the oxygen concentration (Cronin et al. 1999). Reduced water exchange may also affect the fish health, as the ammonia levels in cages may increase compared to those of the surrounding waters.

Factors Influencing the Fish Disease Risk

Biofouling has been reported to be a risk factor. Fouling communities may pose health risks to cultured fish species because they can act as reservoirs for pathogenic microorganisms that exist within large fouling species or in a wide range of microbial communities on cage netting (Meyers 1984). Marine aquaculture may lead to unusual parasitic infections caused by farming in new geographic areas or in net pen environments (Kent 2000). The occurrence of caged fish diseases is also linked to the consumption of fouling organisms by cultured fish species (Andersen et al. 1993). Fouling communities may directly affect fish by causing physical damage to the cultured species. Moreover, a severely fouled net can also support the existence of the free swimming stage of sea lice (*Lepeophtheirus salmonis*) (Kent et al. 1995).

Nevertheless, biofouling organisms may also reduce the disease risk. The potential for the mussel *Mytilus edulis* to harbor bacterial kidney disease makes the survival of the bacterium *Renibacterium salmoninarum* unlikely. These mussels kill the majority of *R. salmoninarum* during digestion and may reduce the level of pathogenic bacteria in the cage environment (Paclibare et al. 1994).

Cage Deformation and Structural Fatigue

Exposure to currents causes net cages to change their shape through deflection and deformation (Fredheim 2005). The extent of this shape change depends on the flow velocity, the original shape and construction of the cage, the placement of weights, the type of net, and the degree of biofouling (Lader et al. 2008). An increase in mesh occlusion will significantly increase the drag

forces on mesh netting. Milne (1970) measured the current forces on clean and fouled nets under different current velocities and showed that the forces on a fouled net may be 12.5 times greater than those on a clean net. Consequently, unless the cage is heavily weighed, the shape of the cage may be severely distorted by the current flow (Osawa et al. 1985). Aarsnes et al. (1990) calculated the deformation rate of a 12,000 m³ cage with a bottom weight of 400 kg and found that the cage volume was reduced by 45% (to 6600 m³) and 80% (to 2300 m³) under velocities of 0.5 m/s and 1 m/s, respectively. Wee (1979) observed a 50% reduction in the volume of a heavily fouled cage in use. Reducing the cage volume may affect the fish health, as the oxygen consumption and ammonia production are expected to increase per unit volume and crowding is likely to stress the cultured fishes.

Lader et al. (2008) analyzed the influence of incoming currents of varying velocities on the deformations of net cages. They found that a current velocity of 0.35 m/s resulted in a 40% reduction in the cage volume. Highly deformed nets increased the structural stress of the cage. Although increasing the cage weight could reduce the deformation, the structural stress will increase (Anon 1993). Tomi et al. (1979) indicated that the weight added to cage corners caused a two- to six-fold increase in the horizontal forces on the cage. Specifically, with heavy weighting, waves cause the floating frame to move upward, and the weight pulls the net down. The structural loading and fatigue may further increase when predator netting is attached to cages.

The biomass of the fouling community usually directly impacts the static load of net cages, which may increase the weight of cages by a factor of 200 (Beveridge 2004). This additional load must be considered in the design of floating and mooring systems. Failure to do so may incur net failures or breakage, which have been devastating for commercial mariculture (Huguenin 1997). In addition, Swift et al. (2006) measured the increase in the fluid resistance in net cages due to biofouling. Biofouling resistance coefficients generally increase with increasing solids (ratio of projected area to defined area) and biomass, and the

resistance of fouled nets may be more than three times that of clean nets.

Summary of Biofouling Impacts

Biofouling in marine cages can lead to mesh clogging, resulting in decreased productivity and health risks to fishes as well as structural fatigue and cage deformation. Furthermore, biofouling is a critical management issue. If the impact of biofouling is not adequately considered, the costs of operation and maintenance will increase.

Surprisingly, there is little information about the effects of fouling, a problem of such high impact, and this aspect is only now beginning to be discussed in detail. Considering the limited products available to control aquaculture fouling, a quantitative study of the spatiotemporal variation of biofouling communities at the species level, as well as the impacts of animal husbandry and farm management on fouling development, can help the mariculture industry to choose the most cost-effective fouling control method.

The rapid development of cage aquaculture in tropical and subtropical areas, in which biofouling occurs most rapidly, and the shift to offshore cage mariculture with limited coastal space poses new challenges to understanding the impact of biofouling, especially to implementing successful marine fouling control strategies.

Principles of Controlling Biofouling

Physical Approach

In view of the serious impact of biofouling in commercial fish farms employing cage culture, protective measures typically involve a variety of methods to control net fouling, usually including the utilization of farm management techniques, namely, frequently changing and cleaning the netting, and the use of antifouling coatings. In the following, these methods are reviewed along with the upcoming options for the nonbiocidal control of biofouling in marine aquaculture. This aspect is particularly important because of the restrictions on the application of traditional metal-based coatings in the aquaculture industry.

Net Changing

In almost all parts of the world, fouling develops rapidly at a certain stage in use. Frequently replacing and cleaning nets are essential practices to maintain water exchange within cages. The replacement rate of a large mesh cage is relatively low because critical mesh blockage or occlusion occurs only under a considerable amount of biofouling. Although nets are frequently changed in temperate and tropical regions, cages immersed in offshore locations and extremely cold water can be immersed in water for a considerably long period without cleaning. Moreover, the cleaning frequency can be delayed to a certain extent by raising the top several meters of the cage above the water surface (Needham 1988); however, this technique is only applicable to the case in which the fouling is limited to the upper area of the cage.

Net changing may incur considerable costs in mariculture, and it is necessary to purchase a large number of nets and support dedicated net replacement and cleaning teams. In addition, frequent net changes may result in the damage or loss of fish in the cages and interrupt or disturb feeding, which may reduce the fish growth rate. However, the economic impacts of fouling and fouling control on the aquaculture industry cannot be quantified at present.

Shore-Based Net Cleaning

Usually, biofouling communities are removed from netting cages by replacing the fouled nets and transporting them to the shore for manual or semiautomatic cleaning (Lewis 1994a). However, the frequent replacement of nets in standard floating cages is labor- and capital-intensive, and large-scale cages require marine hydraulic cranes. Furthermore, washing procedures and the handling of nets often cause damage to nets and shorten their service life.

Underwater Net Cleaning

Underwater cleaning is feasible and commercially plausible; however, this approach usually requires diving, and thus, it is more expensive and dangerous than shore-based cleaning. An Australian company tested the efficacy of an underwater net cleaner, which could prevent biofouling for

10 weeks in summer (Hodson et al. 1997). However, due to physical constraints, the fouling organisms in the net grid or crevices were not completely removed, leading to the rapid regrowth and recolonization of the fouling organisms.

Many cleaning practices have been adopted in Norway. Three main strategies are employed to address biofouling on fishing nets, including cleaning nets onshore and in situ. Copper-based coatings are also used on cage netting in combination with regular on-site cleaning.

Biological Control

Increased profitability and sustainability can be achieved through the smart use of herbivorous fish or invertebrates to control biofouling (Beveridge 2004) and the use of benthic/debris feeders to remove uneaten food (Angel et al. 2002). The concept of biological control is limited by the dramatic changes in the fouling types of algae and invertebrates, which indicates that only herbivores and omnivores with extensive feeding habits are successful control agents. Furthermore, continuous grazing may provide a selective environment for nonfood species, and thus, polyculture may only reduce the frequency of net changes. For example, using sea urchins and resident crabs for biological control has been demonstrated to be effective in controlling the fouling of suspended shellfish systems (Lodeiros and Garcia 2004; Ross et al. 2004). In the case of finfish, biological control of fouling has been successful with the coculture of other finfish (Chua and Teng 1980).

In salmon aquaculture, detritivorous animals such as red sea cucumbers, *Parastichopus californicus*, which feed on broken or rotten food, have been shown to effectively reduce the growth of fouling organisms. However, due to the negative effects of wave-generated undulation, sea cucumbers cannot maintain their position on both sides of the cages suspended with buoys, although they can maintain their position in rigid frame pens (Ahlgren 1998). The advantage of polyculture with the sea cucumber is that sea

cucumbers are a key commercial aquaculture product, and there is a large demand for sea cucumbers in Asian markets (Conand and Sloan 1989).

Alternative Cage Designs

Another alternative to frequent net changing and underwater cleaning is the utilization of totally enclosed rotating cages (Willinsky et al. 1991). Such cages are either horizontally mounted cylinders rotating on a central axis (Menton and Allen 1991) or rectangular boxes with inflatable buoyancy devices at each corner. The rectangular cage rotates gradually by changing the buoyancy of the corners in turn (by inflation and deflation or by displacement and water filling). When using a rotatable cage, no area of the net needs to be immersed for a long time, and the net can be brought to the surface to air dry, thereby killing the attached biofouling. In addition, the cage can easily remove biofouling and help repair the net; moreover, significant growth of biofouling can be avoided by keeping the net immersed for only a short period of time. Blair et al. (1982) noted that a cage rotation of 90° per week was sufficient to keep cages basically free from biofouling. Geffen (1979) reported that cage rotation every 3 days could help keep cages completely clean.

Although completely enclosed and rotating cages have many other benefits, such as preventing birds from predation and avoiding storms and ice by cage submergence, rotating cages are not widely utilized. To hold volumes of fish comparable to conventional floating collars with a circumference >90 m, it would be necessary to construct extremely large rotating cages. Furthermore, commercial rotating cages are more expensive than traditional designs, and continuous exposure to direct sunlight can hasten the degradation of nets (Beveridge 2004).

Protective Coatings with Antifoulants

In the last 50 years, antifouling coatings have been intensively investigated. Chemical antifouling agents in coatings prevent the formation and establishment of marine biofilms through the leaching of bactericide, which can produce a thin layer of toxic solution around the net. Some of the

earliest published cage antifouling tests indicate that the antifouling agent keeps the net completely clean for 5 months, during which the untreated fishing net is completely blocked (Koops 1971).

However, only a few antifouling products have been specially designed for aquaculture cages, and the industry has typically learned from other marine industries, especially the shipping industry. Therefore, several antifouling products that contain chemicals and heavy metals clearly recognized as harmful to the environment have been used in the aquaculture industry. Sufficient public concern has been voiced regarding the use of these chemicals in aquaculture, particularly antibiotics and antifouling agents (Costello et al. 2001). Therefore, the broader aquaculture industry, including producers, regulators and research providers, must conceptually and realistically develop a safe industrial alternative.

Toxicity of Heavy Metal Organic Compounds

Tributyltin (TBT), one of the most widely used and “successful” (in addressing biofouling) antifouling agents on ship hulls since the 1960s (Yebra et al. 2004), is a broad-spectrum algicide, fungicide, insecticide, and acaricide. Because of its antifouling effect, TBT is also widely used as a cage coating in mariculture.

However, the use of TBT antifouling agents has demonstrated several hazards related to toxic coatings in mariculture (Terlizzi et al. 2001). TBT seeped from an impregnated net was recorded in the water around the treated cage (Balls 1987); in addition, the release of TBT from a newly coated cage was measured, with Sn contents of 1 mg/m³, 0.1 mg/m³, and 0.005 mg/m³ discovered after 1 day, 2 weeks, and 5 months, respectively.

The use of TBT-impregnated nets in salmon aquaculture resulted in histopathological effects (Bruno and Ellis 1988) and mortality (Lee et al. 1985). Moreover, salmon raised in treated nets could rapidly bioaccumulate TBT. Short and Thrower (1986) reported bioaccumulation after 3–4 days of exposure to 1.5 pg/L. The authors recorded wet weights of 6.4, 1.9, and 0.3 pg TBT/g for the liver, brain, and muscle, respectively.

Moreover, TBT antifouling products pose an unacceptable risk to nontarget species, which cannot be identified when introduced in the market. Furthermore, TBT induces sexual aberrations in gastropods (Gibbs et al. 1991) and has since been found in fish, bivalves, seabirds, and marine mammals (Terlizzi et al. 2001 review).

The adverse effects of the widespread use of TBT have led to a ban on its use (Evans 1999). In 1986, the National Farmers' Union of Scotland voluntarily participated in the prohibition of its use on fish cages, and in 1987, the Scottish government banned its retail sale (Balls 1987). The International Maritime Organization has banned the use of TBT in coatings since 2003 (Julian 1999), and many governments have thus prohibited the use of organotin in antifouling coatings (Costello et al. 2001).

The aquaculture industry is facing future developmental challenges. To ensure that similar TBT scenarios are not repeated, the six criteria followed by the aquaculture industry are as follows (Lewis 1994b): (1) must be effective for a wide range of fouling groups, (2) must be harmless to the environment, (3) must exert no negative impact on the cultured species, (4) must leave no residues in cultured species, (5) must be capable of withstanding onshore handling and cleaning, and (6) must be economically feasible.

Feasibility of Copper-Containing Coatings

After the implementation of the TBT ban, people soon focused on copper- and copper-containing coatings, which have a long history of applications in shipping and mariculture (Lewis 1994b). The main active components in copper-based antifouling agents are cuprous oxide and copper. Copper is leached from the coating of impregnated nets into seawater. To prevent barnacles and diatoms from adhering and growing, leaching rates of 10 and 20 $\mu\text{g}/\text{cm}^2/\text{day}$ should be applied for response treatments and measures, respectively (Callow 1999). However, relatively low concentrations of copper are known to be harmful to fish and many marine organisms, especially invertebrate larvae, and toxicity studies have reported diverse effects (Brooks and Mahnken 2003). Furthermore, in salmon farms, the

intestinal copper content of green sea urchins was noted to be increased (Chou et al. 2003), and copper bioaccumulation was found in the hepatopancreas and oysters of crayfish sampled near the salmon farm (Chou et al. 2000).

Fish are likely to be exposed to antifouling agents for long periods, up to several months. Therefore, from a "clean and green" marketing perspective, the use of toxic metal antifouling agents, i.e., simply using copper as an antifouling compound, is relatively undesirable. At present, most countries are committed to reducing the use of copper-based antifouling agents in the short term.

Other Biocides

Many other biocides are currently used as antifouling agents worldwide; although these products are not necessarily used in mariculture (Konstantinou 2006), they are potential candidates to supplement or replace copper as an antifouling agent. The most commonly used biocides include chlorothalonil, dichlofluanid, diuron, irgarol 1051, sea-nine 211, thiram, TCMS (2,3,5,6-tetrachloro-4-methylsulfonyl), pyridine, pyrithiones, TCMTB (2-thiocyanomethylthiobenzo-thiazole), zinc pyrithione, and zineb (Konstantinou 2006). Coatings using isothiazolinones as the sole biocide have been successfully tested in Australia (Svane et al. 2006); however, little peer-reviewed literature exists on the efficacy of other biocides tested in aquaculture environments.

The known chemical and physical properties of common biocides vary widely, and their properties, toxicity, environmental fate, and knowledge gaps in the aquatic environment have been extensively reviewed (Konstantinou and Albanis 2004; Konstantinou 2006). A potential danger remains because the listed biocides are largely untested in some cases, and they may be less efficient and/or more harmful to the environment than TBT or copper (Evans 1999). Moreover, the biocides released during the cleaning process persist in the environment when associated with paint particles (Thomas et al. 2003). Considering the gaps in our understanding of the long-term effects of biocides, it is difficult to assess their impacts

Net Structures: Biofouling and Antifouling, Table 1 Key data for a comparative environmental assessment of relevant biocides

	Persistence ^a	Toxicity	Bioaccumulation	Performance ^b
Chlorothalonil	No			Poor
Dichlofluanid	No			Poor
Diuron	Yes	Least	No	Poor
Irgarol 1051	Yes	Least	Yes	Poor
Sea-Nine 211	No		No	Poor
Zinc pyrithione	No			Best
Zineb			No	Best
Thiram			No	
Pyrithiones		High		
Pyridine				Poor
TCMTB				Poor
TCMS				Poor

^apersists in the water column

^bhighest performance in terms of environmental parameters; TCMS pyridine and TCMTB demonstrate environmental characteristics similar to TBT (Voulvoulis et al. 2002)

and risks on the aquatic environment; therefore, effective environmental policies must be formulated according to precautionary principles. Key data are presented in Table 1 regarding a comparative environmental assessment of biocides (Voulvoulis et al. 2002).

To date, all developed synergistic biocides affect the water environment, and no ideal substitute exists for TBT or copper. Moreover, the aquatic environment is affected by booster biocides, and no ideal replacement exists for either TBT or copper. The focus of future research and development has shifted to both effective and environmentally friendly antifouling agents in terms of their chemical (nontoxic coatings) and physical properties (fouling release coatings and nonleaching biocides) (Yebra et al. 2004).

Development of Environmentally Benign Coatings

Natural Biocide Products

Natural products have had a long history in aquaculture. Before using modern polymer-based netting, farmers in Malaysia soaked cotton nets with tannins extracted from the bark of mangroves (*Rhizophora sp.*). Tannins are toxic and function as natural biocides. These tannins have a high

absorption capacity for traditional fiber nets but low absorption capacity for synthetic materials, and the effectiveness is usually short term (Lai et al. 1993).

However, the potential for the use of natural antifouling agents is limited because they are simply another chemical entity, and considerable commercial development time is required in the regulatory and commercial environment to prepare surface effect coatings. This kind of compound must be synthesized in large quantities at a reasonable cost, added to the coating matrix, and subject to the same regulatory assessment as biocides by environmental agencies before its practical application can be formally adopted. Fusetani and Clare (2006) comprehensively reviewed antifouling compounds from natural sources, including potential effective compounds.

Fouling Release Coatings

In recent years, research has focused on biocide-free low surface energy siloxane elastomers and fluoropolymers, which may provide a nontoxic alternative to control biofouling and facilitate the application of such coating products (Yebra et al. 2004; Chambers et al. 2006). These “fouling release” coatings are designed to reduce or prevent the adhesion of biofouling, and silicone-based coatings are not toxic to any tested

organism (Karlsson and Eklund 2004). Nevertheless, nets and panels coated with nontoxic silicone effectively reduce the initial stage of fouling development and make it easier to remove the accumulated biofouling (Hodson et al. 2000; Terlizzi et al. 2000). At present, these materials are considered substitutes for toxic coatings on the surface of ship hulls, for which the speed of the vessel produces the hydrodynamic shear force required for loosely attached biofouling to fall off (Yebra et al. 2004).

However, the commercial development of these technologies and their application in fixed aquaculture infrastructure are difficult, and research to solve these problems requires additional time. The principle of superhydrophobicity has been further developed in the field of fouling release technology (Genzer and Efimenko 2006; Marmur 2006). This principle can likely be combined with the abovementioned technologies to solve the biofouling problem of relatively static cage nettings.

Nonleaching Biocides Coatings: Contact Type

Biocides that irreversibly bind (via covalent bond grafting) to the surface of antifouling coatings or antifouling nets are called nonleaching biocides (Clarkson and Evans 1993, 1995). Although this approach can limit environmental contamination, it has not been successfully implemented, possibly due to technical problems and a wide range of fouling organisms, many of which may not respond to bound biocide entities. These technologies have been effectively used to inhibit the biological attachment and growth of bacteria on biomedical devices (Hume et al. 2004; Zhu et al. 2008). Under legislation restricting antifouling technology to a nonrelease mechanism, this aspect may be promising with broad prospects (Silva et al. 2019).

Microtexturing of Surfaces

Research on the identification of physical defenses against biofouling in specific animals and plants may also have commercial applications in antifouling technologies. Such methods are characterized by topography and microstructure surfaces to prevent the attachment of common

fouling organisms. For instance, natural regular rippled surface features have been visualized on blue mussels (Scardino et al. 2003), and these structures significantly inhibit the settlement and development of biofouling (Scardino and de NYS 2004).

Surface microtopographies, many with a bioinspired design, inhibit the attachment and growth of specific fouling organisms and promote their release (Scardino et al. 2006, 2008). In many cases, the efficacy depends on the proportion of morphology, i.e., micro/nanostructures, relative to the size of the settled larvae or propagules, which limits the surface effectiveness to a limited range of fouling organisms. To enhance the effectiveness of prevention or broaden their deterrent impacts, surfaces with multiple scales of topography are now being developed (Schumacher et al. 2007). This nonleaching surface effect technology can be used in combination with fouling release coatings and may be effective in preventing biofouling in aquaculture, in which the dominant single species in the fouling community can be targeted.

Conclusions

At present, methods of protecting against fouling on fishing nets and other aquaculture structures are relatively limited, and most of them are based on the release of copper and zinc by adding booster biocides. The use of zinc and copper is restricted by the International Convention on the elimination of zinc, and thus, the use of such products may be limited as well. Consequently, specific biocides with a low environmental impact are the only mechanism for biofouling control. However, new products can be developed with emphasis on antifouling technologies based on low surface energy (foulant-release) coatings, textures, and surface-bound compounds. Unfortunately, the fouling release technology mainly depends on the hydrodynamic force to remove fouling organisms with low adhesion on the fouling-release surface, making such methods less suitable for aquaculture. Moreover, with the continuous improvement of vessel antifouling technology, the transfer of technology to

aquaculture industries is expected to become more feasible, and product development is expected to be targeted at larger aquaculture industries. Another alternative to heavy metal and biocide technologies, biological control, has yet to be proven to have broad-spectrum efficacy in controlling biofouling.

Although such methods are industry- and site-specific and it is difficult to envision their wide application, certain industry sectors may significantly benefit. On the other hand, with the withdrawal of technologies based on metals and biocides from the market, the aquaculture industry is expected to become greener and environmentally friendly. More and better technologies are expected to emerge as solutions for biofouling protection.

Net Structures: Design

Fukun Gui

National Engineering Research Center for Marine Aquaculture, Zhejiang Ocean University, Zhejiang, China

Synonyms

Copper Alloy Net; Metal Net; Polyamide (PA) Net; Polyethylene (PE) Net; Ultrahigh Molecular Weight Polyethylene (UHMWPE) Fiber Net

Introduction

A net is a porous structure composed of net twine constructed by twisting and weaving. Nets are commonly applied in fishery production (e.g., fishing industry, cage aquaculture, and net enclosure aquaculture) and engineering construction (e.g., building protection and area isolation). In this chapter, we describe the application design of

a net in cage aquaculture and net enclosure aquaculture (NEA).

Net Types

In practice, synthetic fibers, metals, and other new types of materials are commonly used for net making. Among these materials, polyethylene nets, polyamide (PA) nets, ultrahigh molecular weight polyethylene (UHMWPE) fiber nets, polyester PET (polyethylene terephthalate) nets, copper alloy nets, and coated metal wire nets have been widely used in cage aquaculture and NEA (see Fig. 1).

Polyethylene (PE) Net: Polyethylene monofilaments are twisted to form net twines and later woven to form a net. Polyethylene is flexible and exhibits a high tensile strength, high impact resistance, and low density (less dense than water, approximately 953 kg/m^3). The net twine used in PE nets is normally composed of 3 strands, and the number of monofilaments per strand is set according to the mesh size and twine strength. PE netting is one of the most widely used net types in cage aquaculture.

Polyamide (PA) Net: Polyamide, commonly known as nylon (nylon), was invented in the early 1930s and rapidly became the leading industrial product of polymer synthetic fibers. Its favorable characteristics include its high strength, high abrasion resistance and good elasticity, and the density (approximately 1140 kg/m^3) is slightly higher than that of water. Generally, the single-yarn diameter of PA fibers used as net materials is 0.66–2.22 tex, considerably smaller than that (36 tex) of PE monofilaments. Under the same diameter, the breaking strength of PA fibers is generally slightly higher than that of PE fibers.

Ultrahigh Molecular Weight Polyethylene UHMWPE Fiber Net: UHMWPE fiber was successfully developed by the DSM company (Netherlands) in 1979. This net has many advantages, such as a high strength, low density, high fatigue resistance, and low temperature resistance. This material was once used to prepare bullet-proof jackets. Research has demonstrated that the strength of a net cable woven from UHMWPE fibers is 3–4 times that of a PE net cable, demonstrating a considerable advantage in strength.

Net Structures: Design, Fig. 1 Nets commonly used in the farming industry (by Fukun Gui)

However, the UHMWPE fiber weaving process is more complicated than that of PE netting, and the price of a UHMWPE fiber net is 5–6 times that of a PE net. Therefore, UHMWPE fiber nets are often applied in important aquaculture projects with high manufacturing costs (such as cage aquaculture projects in the open sea and large-scale NEA projects).

Polyester (PET) Net: The PET net is a newly developed net that exhibits a hexagonal mesh structure made of a monofilament structure through a special twisting process. The diameter of a PET net monofilament is generally approximately 2.5–4 mm, and the strength is approximately 1–1.5 times higher than that of an ordinary PE net with the same diameter but lower than that of a UHMWPE net. PET nets exhibit an excellent fatigue resistance strength. Owing to the monofilament structure, the surface of the net is smooth and has no voids. Moreover, the biofouling rate is lower than that of other fiber nets, which helps to relieve the impacts on nets from currents and waves. Furthermore, the price of a PET net is close to that of a UHMWPE net, and the comprehensive cost-performance ratio of

PET nets is higher. The PET net has been gradually applied in key farming projects.

Metal Net: Metal nets in farming projects are usually made of copper alloy wire or steel wire coated by nickel-zinc. The abovementioned metal nets exhibit excellent antifouling characteristics, and thus, they have been applied in cage aquaculture and NEA projects. However, the application of copper alloy nets is restrained by their high cost compared with other types of nets currently used in farming projects.

Key Technologies in Net Design

The design of the net system in aquaculture projects generally requires several key procedures, such as the net model design and material selection, net load calculation, net strength design, and net assembly design.

Net Model Design and Material Selection

The selection and design of nets are mainly based on the functional requirements of aquaculture. Generally, the following main factors are considered:

Mesh Size Generally, the mesh size of the net should be chosen according to the actual size and body characteristics of the farming fishes. For small fish fry, the mesh size of the net can be small. For large fish fry, a larger mesh size should be selected to ensure sufficient water exchange. In the entire farming process, as the body length of the fishes increases, the nets should be replaced over time by nets with larger meshes. Therefore, it is necessary to rationally design nets with several different mesh sizes.

Preliminary Selection of the Twine Diameter First, the net load strength must be calculated to determine the diameter of the net twine. The selection of the twine diameter depends on not only the strength requirements but also the weaving process of the mesh. A certain relationship exists between the twine diameter and mesh size of the net. Smaller meshes generally adopt a smaller diameter of twine. Choosing a twine diameter that is excessively large may lead to the failure of net fabrication. Under normal circumstances, the twine diameter is initially determined according to the mesh size and later optimized according to the load strength of the net. In terms of the twine diameter of the polyethylene net, Table 1 (Shi et al. 2016) can be referred to for the preliminary selection.

When the mesh size exceeds 40 mm, the number of twine strands varies according to the practical use. The corresponding twine diameter can be estimated according to formula (1):

$$D = 0.022 \times G + 1.1865 \quad (1)$$

where D represents the twine diameter and G represents the number of twine strands.

Selection of the Net Material When choosing the net material, several key factors should be carefully considered, such as the cost of the net, the demanded strength and toughness, and the antifouling capability. Among the nets commonly used in aquaculture projects, copper alloy nets exhibit a favorable antifouling performance. However, they are the most expensive option, and their toughness is insufficient. UHMWPE fiber nets exhibit excellent strength, but the cost is relatively high, and their antifouling function is inadequate. PET nets have a relatively high tensile strength and excellent fatigue strength, and their antifouling performance is higher than that of other fiber nets; however, the cost is also high. For the PE net, the overall strength is lower than that of the abovementioned materials, and the antifouling functionality is lacking; however, PE nets are inexpensive, which contributes to their higher cost-performance ratio. Therefore, PE nets have been widely used in aquaculture projects. In recent years, the development of large-scale deep-sea aquaculture equipment and ultra-large NEA equipment has imposed higher requirements on the strength of the net; therefore, UHMWPE fiber nets and PET nets are attracting increasing attention.

Calculation of the Net Load

The net load is an important basis for the net design. The selection of the net material and twine diameter is based on the calculated net load. Three methods can be used to calculate the net load: theoretical analysis, physical model testing, and numerical simulation. Regardless of which method is adopted, the design standard of

Net Structures: Design, Table 1 General specifications of the PE net

Mesh size (mm)	Twine specification	Twine diameter (mm)	Weight (g/100 m)	Breaking strength (kgf)
0.5–1	0.23/1	0.23	4.36	2.37
1–2	0.23/1×2	0.46	9.33	3.55
3–10	0.23/1×3	0.53	14.0	5.32
10–13	0.23/2×2	0.67	17.0	6.62
13–20	0.23/2×3	0.78	28.0	9.94
20–25	0.23/3×3	0.96	42.0	14.9
25–30	0.23/4×3	1.13	56.0	18.4
30–40	0.23/5×3	1.29	67.0	23.0

the farming project must be determined first. The selection of the design criterion for a farming project depends on the conditions of the sea area in which the farming facility is located and the importance and influence of the farming project. For general near-shore cage culture, the design criterion is generally set to once every 25 years. For aquaculture projects in offshore waters, a design criterion of once every 50 years is recommended. For large-scale sea cage aquaculture in the outer sea and NEA projects, the design criterion is generally set to once every 100 years due to their significance and influence.

Theoretical Analysis Method The core purpose of the net load calculation is to determine the load strength of the key parts in the net system. Necessary simplifications and assumptions to the calculation model are often implemented when carrying out a theoretical analysis of the net load in aquaculture engineering.

The flow load acting on the net unit can be calculated by the general hydrodynamics equation (2):

$$F_D = \frac{1}{2} \rho \cdot C_D \cdot A \cdot u^2 \quad (2)$$

where F_D represents the flow force acting on the net; ρ represents the fluid density; C_D represents the drag coefficient of the net; A represents the projected area of the net; and u represents the fluid velocity.

The inertial force produced by unsteady flow dynamics can often be ignored due to the small-scale structure of the net, and thus, formula (2) can be applied to a net force analysis under wave conditions with u representing the fluid point velocity. The net load is calculated by the Stokes finite amplitude wave theory and Airy linear wave theory in deep-water sea cage aquaculture engineering. The third- or fifth-order Stokes finite amplitude wave theory can be used to calculate the net load when cage aquaculture or NEA projects are constructed in shallow waters. However, when the water depth is extremely shallow or there is a shore-linking section (such as shore-linked NEA), the theoretical calculation may

induce a large error, and it is generally necessary to carry out a special study.

The drag coefficient C_D is related to the impact angle of the current, Reynolds number, and solidity of the net and other parameters. According to the existing research literature (Li and Gui 2005), the drag coefficient of the mesh twine can be calculated by the following formula when analyzing the force of the net:

$$C_{D90} = 3(\text{Re})^{-0.04} \quad (3)$$

$$C_{D\theta} = C_{D90} (1 - \cos^2 \theta \cos^2 \varphi + \sqrt{S_n} \cos^2 \theta \sin \varphi \cos^3 \varphi - 3S_n \cos^3 \theta \sin^2 \varphi) \quad (4)$$

Regarding the drag coefficient of the knot, Fredheim and Faltinsen (2003) suggested that it is reasonable to use a drag coefficient in the range of 1.0–2.0 when modeling the knot part as a sphere.

The projected area of the mesh is related to the impact angle of the mesh unit and mesh structure. In general, the net mesh has rhomboidal, rectangular, and hexagonal structures, which can be classified into nodular and nonnodular types. Rhomboidal and hexagonal meshes are the most commonly used. A rhomboidal mesh consists of four wires and four knots, as shown in Fig. 2. A knot is shared by four meshes, and a twine is shared by two meshes; specifically, a mesh consists of a knot and two mesh twines, as shown in Fig. 3. Therefore, this definition is used when calculating the projected area of the mesh.

The inclination should be considered to calculate the projection area of a rhomboidal mesh when the mesh is slanted. Assuming that the angle between the mesh and direction of water flow is θ , the projected area of the mesh unit can be calculated as follows (Gui 2006):

$$A = a \cdot d \cdot \sqrt{\mu_1^2 + \mu_2^2} \cdot \sin^2 \theta \cdot N \quad (5)$$

where A represents the projection area of the net; a and d represent the length and diameter of the twine, respectively; μ_1 and μ_2 denote the hanging

Net Structures: Design, Fig. 2 Sketch of a diamond mesh (Gui 2006)

Net Structures: Design, Fig. 4 Sketch of a hexagonal mesh (Gui 2006)

Net Structures: Design, Fig. 3 Definition of a single diamond mesh (Gui 2006)

Net Structures: Design, Fig. 5 Definition of a single hexagonal mesh (Gui 2006)

ratio in the horizontal and vertical directions, respectively; and N refers to the total number of meshes in the net unit.

For a hexagonal mesh without knots, as shown in Fig. 4, the calculated features mainly include the height H and width L of the mesh, length a_1 and diameter d_1 of the bevel mesh, and length a_2 and diameter d_2 of the vertical mesh. In the case of a certain inclination angle, the expressions to calculate the projected area of different mesh segments are different, and these aspects should thus be considered separately in the calculation. Similar to a mesh with knots, one mesh is equivalent to one twine with diameter d_1 and length a_1 and two twines with diameter d_2 and length a_2 , as shown in Figs. 4 and 5. The calculation of the projected area of a mesh can start from the calculation of the projected area of a single mesh. Assuming that

the impact angle between the plane net and the water flow is θ , the projected area of the plane net at this impact angle can be calculated according to the following formula.

$$A = \left(a_1 d_1 \sin \theta + d_2 \cdot \sqrt{(L - d_1)^2 - (H - 2a_1)^2 \cdot \sin^2 \theta} \right) \cdot N \quad (6)$$

where A is the projected area of the mesh, θ represents the water impulse angle, and N denotes the total number of meshes in the net unit.

A general biofouling situation will occur in the fiber net after marine farming for a certain period,

leading to an increase in the projected area of the net. In the actual calculation, the effect of biofouling should be considered.

Physical Model Tests

Modeling Criteria for Fishing Nets in Experiments Model experiments are highly useful for examining the hydrodynamic characteristics of fishing nets; however, it is challenging to establish reasonable simulation criteria for the model tests of fishing nets. For such model tests, the geometric scale λ is usually greater than 20:1. If the model net is designed strictly according to geometric similarity principles, two challenges arise. First, the yarn used for the model net will be extremely thin, which renders the manufacturing process difficult. Second, the Reynolds number (Re) for the model net will change significantly because the mesh is modeled to be extremely small, leading to a large difference in the hydrodynamic behavior between the model and prototype nets. Thus, special simulation methods must be used. Tauti's criteria (Tauti 1934), which were developed in the 1930s during research into fishing net problems, are used only for conditions where a current is present.

Tauti's Simulation Criteria Tauti's simulation criteria involve two geometric scales for nets, λ and λ' , which represent the global and model mesh scales, respectively:

$$\lambda = \frac{L_p}{L_m} \text{ and } \lambda' = \frac{d_p}{d_m} = \frac{a_p}{a_m}, \quad (7)$$

where d is the filament diameter, a is half the mesh size, and subscripts p and m denote the model and prototype sizes, respectively. Based on the geometric similarity and dynamic similarity, the following expressions can be obtained according to Fig. 6:

$$\frac{W_p S_p}{W_m S_m} = \frac{r_p S_p}{r_m S_m} = \frac{T_p L_p}{T_m L_m} = \frac{F_p}{F_m}, \quad (8)$$

where W and r denote the gravity and hydrodynamic force per unit area on the net, respectively, and T is the force per unit length on the net edge. When the net material is the same for the model and the prototype, the equation can be replaced by

$$\lambda^2 \lambda' = \lambda^2 \frac{V_p^2}{V_m^2} = \lambda \frac{T_p}{T_m} = \frac{F_p}{F_m} \quad (9)$$

In trawl experiments, Tauti's simulation criteria are suitable and widely used. However, in model tests of net cages, two limitations arise for practical experiments. First, in model tests, the model mesh scale cannot be excessively large, and thus, a greater current velocity is required. Second, Tauti's simulation criteria cannot be applied to model tests under wave conditions because Eq. (9) is not satisfied if geometric similarity is applied in the presence of waves. Thus, for model tests of net cages under wave and current conditions, the following gravity simulation criteria are recommended.

Net Structures: Design, Fig. 6 Model to calculate forces acting on a micro-segment of a fishing net (Gui 2006)

Extended Gravity Simulation Criteria (Gui 2006) The main principles for an extended gravity simulation are as follows:

1. Two geometric scales for the nets are used as in Tauti's simulation criteria: λ and λ' represent the global scale and the model scale for the yarn diameter and net mesh size, respectively.
2. Since the porosity ratio for the model net is the same as that for the prototype, the external forces acting on the net will follow the gravity simulation criteria by a scale of λ^3 .
3. The model net weight simulated by a scale of λ^3 is modified as follows:

$$\Delta W = \left(\frac{1}{\lambda'} - \frac{1}{\lambda} \right) \cdot \left(\frac{\pi d_1^2}{4a_1\mu_1\mu_2} \times 10^4 \right) \cdot (\rho - \rho_w) \cdot q \cdot S, \quad (10)$$

where ρ is the density of the net material, ρ_w is the water density, q is the packing fraction of the filament, S is the area of the net, and μ_1 and μ_2 are the hanging ratios (see Fig. 7) defined in Eqs. (11) and (12), respectively.

In the crosswise direction of the net, the hanging ratio is defined as

$$\mu_1 = a/2L \quad (11)$$

In the longitudinal direction, the ratio is

Net Structures: Design, Fig. 7 Definition of mesh properties (Gui 2006)

$$\mu_2 = b/2L. \quad (12)$$

Based on the gravity simulation criteria, the following equation can be derived:

$$\lambda^3 = \lambda^2 \frac{V_p^2}{V_m^2} = \lambda \frac{T_p}{T_m} = \frac{F_p}{F_m}. \quad (13)$$

Numerical Simulation Method

It is necessary to establish an appropriate calculation model when using a numerical simulation method to analyze the net load. At present, the most widely used method for flexible fiber nets is the lumped-mass model. The finite element method is generally used for more rigid nets, such as those involving a copper mesh, using mature commercial software such as Ansys. Here, we simply introduce a lumped-mass model for flexible fiber nets.

Lumped-Mass Model By applying a lumped-mass model (Li et al. 2006), a fishing net is assumed to be a connected structure with limited masses and springs. The lumped point masses are set at each knot and at the center of each mesh twine (see Fig. 8).

Depending on the use of knots, two different types of nets are commonly used: nets with knotted meshes and nets with knotless meshes. In the model, the diameter of the sphere d reflects the physical properties of the net. For a mesh with knots and a knotless mesh, d is considered to be 3.14-fold and 1.5-fold greater than the diameter of the twine, respectively.

According to Newton's second law, the equation of motion for a lumped mass i in waves can be expressed as

$$M_i a = \sum_{j=1}^n \vec{T}_{ij} + \vec{F}_D + \vec{F}_I + \vec{W} + \vec{B}, \quad (14)$$

where M_i is the lumped mass of point i , a is the acceleration of mass point i , $\vec{T}_{ij}$ is the vector of the tension in twine ij (j represents the knots at the other end of twine ij), n is the number of knots adjacent to point i , $\vec{F}_D$ is the drag force, $\vec{F}_I$ is the inertial force, $\vec{W}$ is the gravity force, and $\vec{B}$ is the

Net Structures: Design, Fig. 8 Schematic of the mass-spring model (Li et al. 2006)

Net Structures: Design, Fig. 9 Sketch of the mesh grouping method (Zhao 2007)

buoyancy force. According to research, the inertial force $\vec{F}_I$ on a fishing net is rather small under wave conditions compared to other external forces and can thus be omitted. The drag force $\vec{F}_D$ can be calculated using equation (2), with the drag force coefficient C_D calculated by equations (3) and (4).

Equation (14) can be solved using Runge-Kutta methods. The net shape and force distribution at each time step can be calculated numerically by solving these ordinary differential equations for a given initial condition.

Mesh Grouping Method When all the knots in the mesh and at the twine are used as mass points,

more than 10,000 mass points exist for a common plane net, for which the calculation time in a practical simulation is extremely large. To reduce the computational cost, a mesh grouping method can be employed in the calculations. The method consists of modeling a given number of actual meshes as a fictitious equivalent mesh that has the same physical qualities as the actual meshes, such as the projected area of the net, specific mass, and weight. Figure 9 shows an example of a 4×4 mesh with 65 lumped mass points that is approximated to a 2×2 mesh with 21 lumped mass points. According to calculations by Zhao (2007), using 1×1 (G0), 2×2 (G4), and 4×4 (G16) meshes to model the same panel yields

Net Structures: Design,**Fig. 10** Comparison of the calculation time for different mesh grouping methods (Zhao 2007)

similar results for the predicted hydrodynamic forces for current-only loading, although with a considerable time reduction, as shown in Fig. 10.

Strength Design of the Net

The wire with the maximum tension in the net is generally considered to have the basic properties for the net strength design after the net load distribution is obtained. The net strength is determined mainly by the diameter of the mesh but is also affected by the knot form and mesh shape. It is still necessary to consider the attenuation of mesh strength caused by aging and biofouling when considering the service life of the net. Therefore, the safety factor K , which equals 3–4, is recommended for net design; specifically, the strength of the net selected for use should be 3–4 times the calculated load. Stress concentration is strictly forbidden to appear when performing net design. If the situation is unavoidable, special protection or reinforcement should be introduced.

Net Assembly Design**Net Sewing**

First, a certain width of net panel is established during net manufacturing, and net cutting and sewing are performed according to the overall structure of the cage or NEA. The common methods of net suturing in aquaculture engineering include braiding and winding.

Braiding involves connecting two pieces of net panels and can be categorized as longitudinal and transverse braiding according to the direction of the braiding mesh, as shown in Fig. 11. The material and diameter of the net line required for knitting should be the same as that of the net. The size of the mesh formed by knitting and the knotting method must also be the same as those for the original net. The net forms a complete and integral unit after knitting, which involves strict requirements in terms of manual weaving techniques.

Winding involves the connection of two net panels. The requirements for winding are relatively approximate, and such methods are generally used for emergency repair or sewing processes, which do not involve high requirements. Winding can be categorized as ordinary winding (see Fig. 12) and cutting winding (see Fig. 13).

Rope Assembly

After the net is sewn, it needs to be assembled with the rope. The rope is an important structure that transfers the net load to the cage frame or NEA posts. It is necessary to consider the net load and select the rope strength by referring to the design principle of the net strength. After the rope has been selected, it is necessary to sew the net evenly on the rope with an appropriate method and ensure that the net forms the expected shrinkage shape. This process is known as rope assembly.

Net Structures: Design, Fig. 11 Net sewing methods (by Fukun Gui) (a) Longitudinal sewing (b) Transverse sewing

Net Structures: Design, Fig. 12 Ordinary winding methods (Shi et al. 2016) (a) Half mesh winding (b) One mesh winding (c) Multimesh winding

The net and rope are generally divided into several parts according to the mesh size and rope length during the course of assembly (see Fig. 14). The parts are marked at equal points and then assembled segment by segment to ensure the uniformity of the mesh distribution. For items with higher overall requirements for the rope assembly, the net is stretched and fixed according to the design size, and then the ropes are sewn onto the net. The ductility of the rope should be considered in the net assembly. The rope should be pre-tensioned before assembly to eliminate the plastic deformation of the rope.

The rope may or may not pass through the mesh during the assembly (see Fig. 15a–c). To ensure a more uniform stress distribution, the rope should ideally not pass through the mesh (see Fig. 15d–e). The material and diameter of the wire used for sewing the net and rope are generally required to be the same as those of the original net. Sewing is usually performed mesh by mesh, and a dead knot is introduced every several meshes when assembling and sewing to ensure that the whole rope does not fall off the net in case a sewing line breaks (see Fig. 15f).

Net Structures: Design, Fig. 13 Cutting winding methods (Shi et al. 2016)

Net Structures: Design, Fig. 14 Physical map of the rope assembly (by Fukun Gui)

Final Assembly of the Net

The final assembly design is performed after the net has been assembled with the rope. Generally, the net has the main force direction. For example, in the case of a fiber net, the trend of the net system is generally the main force direction, as shown in Fig. 16. It is necessary to identify the main direction of the net load to ensure that the main direction of the load of the net twine is consistent with the main direction of the net load of the whole system during the design and final assembly.

In general cage farming projects, the net is generally suspended from the cage floating frame system with the weights attached at the net

bottom. The main direction of the net load is the vertical direction, and thus, the main direction of the net line stress should be in the vertical direction. Therefore, the net is normally assembled vertically in cage aquaculture systems. For a pile-post NEA project, the stress of the net is generally borne by the pile, and the main direction of the net load is transverse. Therefore, the main direction of the stress of the net is horizontal, and the net panels need to be assembled horizontally. For sea cage aquaculture in the open ocean, the main assembly direction of the net can be determined according to the length-width ratio of the net unit. Generally, both horizontal and vertical assemblies are acceptable.

Net Structures: Design, Fig. 15 Schematic of the rope assembly (Shi et al. 2016)

Net Structures: Design,
Fig. 16 Main force
 direction of the net
 (by Fukun Gui)

Net Structures: Design, Fig. 17 Protective design of the net in a pile-post NEA project (by Fukun Gui)

Regardless of what kind of assembly method is adopted for the net, a uniform assembly should be ensured, and the stress concentration phenomenon should be strictly avoided during the net assembly. In assembly situations in which stress concentration cannot be avoided, special design and reinforcement should be implemented.

Protective Design of the Net

In addition to dynamic factors such as water flow and waves, the impact of floating objects should also be considered during net design. A protection net is mainly used to prevent the impact of floating objects such as bamboo and wood with the culturing net. Therefore, the strength of the protection net must be relatively high. Generally, PE ropes with a diameter of more than 6 mm are recommended for use, and the mesh size (2a) is expected to be more than 10 cm according to the main type of floating objects in the sea area.

For cage aquaculture, a protection net can be generally arranged along the cage periphery at a certain distance from the cage group to achieve effective protection and avoid any influence of normal management operations. For pile-post NEA projects, the protection net can be generally arranged on the peripheral piles, and the layout height of the bottom of the protection net is 1 m below the lowest tide (see Fig. 17).

Definition

Net hydrodynamics	Describes the hydrodynamic forces acting on the associated fluid mechanics around and the deformation of a net structure under external environmental loads, such as currents and waves.
-------------------	--

Scientific Fundamentals

Historical Development

Aquaculture is expanding all over the world, and net cages are becoming increasingly prevalent in the aquaculture industry. A thorough understanding of the hydrodynamic characteristics of a net cage is important for the design of the net cage and the welfare of the fish. An important component of a net cage is the fishing net, where the fish are kept and grown. A fishing net is completely submerged and infinitely flexible. When exposed to a current, a fishing net changes its shape to reduce the hydrodynamic force acting on it, and the deformed net in turn affects the flow field around the fishing net. In this way, the flow field and deformation of the fishing net interact and

mutually influence each other. Therefore, it is necessary to consider the hydrodynamics of the fishing net when designing a net cage.

Over the past decade, many researchers have attempted to determine the magnitude of forces caused by the fluid flow through a fishing net (Balash et al. 2009; Bi et al. 2014a; Dong et al. 2008; Fredheim 2005; Patursson 2007; Tsukrov et al. 2011; Zhao et al. 2013a). Some previous studies (Endresen et al. 2013; Lader et al. 2014) investigated the drag characteristics of net structures for fisheries and aquaculture by considering a cylindrical bar as the basic element. However, simply summing the forces acting on all the cylinders/twines of a net structure without representing the geometrical features of the intersections/knots in viscous flow yields unreliable predictions of the total drag (Fredheim 2005). As an alternative approach, a cruciform element that corresponds to one intersection of two cylinders with the length of a mesh bar can be considered as the basic element of the net structure (Bi et al. 2018).

Overall, the reduction in the current downstream of the fishing net has been considered in examining the hydrodynamic force and the effective volume of the net cage. However, in most numerical studies, only a reduction factor was estimated to represent the shielding effect of the fishing net. A numerical model that can consider the fluid–structure interaction between the flow and a flexible net has not been established. As an extension of previous works (Zhao et al. 2013a, b), a coupled fluid–structure model is developed by combining the porous-media fluid model and lumped-mass mechanical model. Using an appropriate iterative scheme, the fluid–structure interaction between the flow and fishing nets can be clarified.

Porous-Media Fluid Model

The porous-media fluid model can simulate the flow field around a plane net. Therefore, the porous-media fluid model is introduced to model a planar fishing net, and the finite volume method is used to solve the governing equations of the numerical model. A brief review of the porous-media fluid model is presented in this section.

The governing equations of the porous-media fluid model are the Navier–Stokes equations:

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho u_i)}{\partial x_i} = 0 \quad (1)$$

$$\begin{aligned} \frac{\partial(\rho u_i)}{\partial t} + \frac{\partial(\rho u_i u_j)}{\partial x_j} = & -\frac{\partial P}{\partial x_i} + \rho g_i \\ & + \frac{\partial}{\partial x_j}(\mu + \mu_t) \\ & \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) + S_i \end{aligned} \quad (2)$$

where t is the time; μ and ρ denote the viscosity and density of the fluid, respectively; μ_t is the eddy viscosity; $P = p + (2/3)\rho k$, where p is the pressure and k is the turbulent kinetic energy; u_i and u_j are the average velocity components; g_i is the acceleration due to gravity; $i, j = 1, 2, 3$ (x, y, z); and S_i is the source term for the momentum equation.

The porous-media fluid model is a hypothetical model that produces the same water-blocking effect as the fishing net by setting the coefficients of the hypothetical porous media. For a flow through porous media, a pressure gradient exists:

$$\nabla p = a\vec{u} + b|\vec{u}|\vec{u} \quad (3)$$

where a and b are constant coefficients and $\vec{u}$ is the flow velocity. This expression was proposed by Forchheimer in 1901 based on Darcy's law. In the case of large porosities (e.g., an array of fixed cylinders), turbulence will occur, and the quadratic term for the frictional force will completely dominate over the viscous term (the linear term). In this case, the linear term is only a fitting term that has no physical meaning and can thus be neglected.

Outside the porous media, the source term for the momentum equation is defined as $S_i = 0$. Inside the porous media, S_i is calculated by the following equation:

$$S_i = -C_{ij} \frac{1}{2} \rho |\vec{u}| \vec{u} \quad (4)$$

where C_{ij} is given by

$$C_{ij} = \begin{pmatrix} C_n & 0 & 0 \\ 0 & C_t & 0 \\ 0 & 0 & C_t \end{pmatrix} \quad (5)$$

where C_{ij} represents the material matrices consisting of porous media resistance coefficients and C_n and C_t represent the normal and tangential resistance coefficients, respectively.

The drag force (F_d) and lift force (F_l) acting on the flow through the porous media can be expressed as follows:

$$\vec{F}_d = C_n \frac{1}{2} \rho \lambda A |\vec{u}| \vec{u} \quad (6)$$

$$\vec{F}_l = C_t \frac{1}{2} \rho \lambda A |\vec{u}| \vec{u} \quad (7)$$

where λ and A represent the thickness and area of the porous media, respectively.

The porous coefficients in Eqs. (6) and (7) can be calculated from the drag and lift forces. Moreover, the drag and lift forces acting on a fishing net are strongly correlated with the features of the net. Therefore, the connection between the net features and the flow field is established using the porous coefficients in the numerical model. Generally, the drag and lift forces of the plane net can be obtained from laboratory experiments or calculated using the Morison equation:

$$F_d = \frac{1}{2} \rho C_d A u^2 \quad (8)$$

$$F_l = \frac{1}{2} \rho C_l A u^2 \quad (9)$$

where C_d and C_l are coefficients that can be calculated using empirical formulas (Bi et al. 2014b).

The porous coefficient C_n can be calculated from a curve fit between the drag forces acting on a plane net and corresponding current velocities using the least squares method when the plane net is oriented normal to the flow. The other coefficient C_t can be obtained when a plane net is oriented at a certain attack angle (see Fig. 1a). In this case, the coefficient C_t should be transformed to $C_{t\alpha}$ using Eq. (10) (Bear 1972). Next, $C_{t\alpha}$ can be

Net Structures: Hydrodynamics, Fig. 1 Definition of the angles α and β : plane nets (a) in the horizontal plane and (b) at an arbitrary position (Bi et al. 2014b)

calculated from a curve fit between the lift forces acting on a plane net and corresponding current velocities using the least squares method.

$$C_{tx} = \frac{C_n - C_t}{2} \sin(2\alpha) \quad (10)$$

where α is the attack angle, defined as the angle between the flow direction and plane net in the horizontal plane, and C_{tx} is the tangential inertial resistance coefficient for the plane net at an attack angle α .

When a plane net is oriented at an arbitrary position (see Fig. 1b), the porous coefficients should be transformed using Eq. (11):

$$\begin{pmatrix} C'_n \\ C'_t \end{pmatrix} = \begin{pmatrix} \sin^2 \alpha \sin^2 \beta & \cos^2 \alpha & \sin^2 \alpha \cos^2 \beta \\ \frac{1}{2} \sin 2\alpha \sin^2 \beta & -\frac{1}{2} \sin 2\alpha & \frac{1}{2} \sin 2\alpha \cos^2 \beta \\ \frac{1}{2} \sin 2\beta & 0 & -\frac{1}{2} \sin 2\beta \end{pmatrix} \begin{pmatrix} C_n \\ C_t \end{pmatrix} \quad (11)$$

where β is the angle between the normal vector of the plane net ($\vec{n}_{en}$) and z-direction. The cosines of α and β can be calculated between the corresponding two vectors.

Lumped-Mass Mechanical Model

The lumped-mass mechanical model is introduced to simplify the fishing net, and the motion

equations can be established mainly based on Newton's second law. Given an initial net configuration, the motion equations can be solved numerically for each lumped-mass point. Finally, the configuration of the net in current can be simulated. The calculation method for the model has been explained in previous studies (Li et al. 2006; Zhao et al. 2007b), and thus, only a brief outline is provided in this section.

Under a uniform current, the motion equations of lumped-mass point i can be expressed as follows:

$$(M_i + \Delta M_i) \vec{a} = \sum_{j=1}^n \vec{T}_{ij} + \vec{F}_d + \vec{B} + \vec{W} \quad (12)$$

where M_i and ΔM_i are the mass and added mass of lumped-mass point i , respectively; $\vec{a}$ is the acceleration of the point; $\vec{T}_{ij}$ is the tension force in twine ij (j is the index for the knot at another end of the bar ij); n is the number of knots adjacent to point i ; and $\vec{F}_d$, $\vec{W}$, and $\vec{B}$ denote the drag force, gravity force, and buoyancy force, respectively.

To consider the direction of the hydrodynamic forces acting on mesh bars, local coordinates (τ , η , ξ) are defined to simplify the procedure (see Fig. 2). The origin of the local coordinate system is set at the center of a mesh bar, and the η -axis lies on the plane, including the τ -axis and flow velocity $\vec{u}$. The drag force on a lumped-mass point in the τ -direction can be obtained from the Morison equation as follows:

Net Structures: Hydrodynamics, Fig. 2 Local coordinate system for a mesh twine (Bi et al. 2014a)

$$F_{D\tau} = -\frac{1}{2} \rho C_{D\tau} A_\tau \left| \vec{V}_\tau - \vec{R}_\tau \right| \left(\vec{V}_\tau - \vec{R}_\tau \right) \quad (13)$$

where $C_{D\tau}$ is the drag coefficient in the τ -direction, A_τ is the projected area of the twine normal to the τ -direction, and $\vec{R}_\tau$ and $\vec{V}_\tau$ are the velocity components of the lumped-mass point and water particle in the τ -direction, respectively. Similar expressions can be applied to the other two components of the drag force, $F_{D\eta}$ and $F_{D\xi}$.

The mesh-grouping method (Tsukrov et al. 2003; Zhao et al. 2007a) is used to reduce the computational effort of the net. Each grouped mesh is defined as a plane-net element (see Fig. 3). The normal vector of the plane-net element ($\vec{n}_{en}$) is calculated as follows:

$$\vec{n}_{en} = \frac{\vec{n}_{i1} \times \vec{n}_{i2}}{|\vec{n}_{i1} \times \vec{n}_{i2}|} \quad (14)$$

where $\vec{n}_{i1}$ and $\vec{n}_{i2}$ are given by

$$\vec{n}_{i1} = \frac{\vec{j}_1 - \vec{i}_1}{|\vec{j}_1 - \vec{i}_1|}, \quad \vec{n}_{i2} = \frac{\vec{i}_2 - \vec{i}_1}{|\vec{i}_2 - \vec{i}_1|} \quad (15)$$

Because of the deformation of the net, the area of a plane-net element is not constant, which influences the solidity of the plane-net element. Consequently, the solidity S_n must be corrected

Net Structures: Hydrodynamics, Fig. 3 Schematic of a plane-net element (Bi et al. 2014b)

based on the varying area of the plane-net element:

$$S'_n = \frac{A}{A'} S_n \quad (16)$$

where S_n and A denote the solidity and area of the undeformed plane-net element, respectively, and S'_n and A' are the corrected solidity and area of the plane-net element, respectively. To calculate the area of the plane-net element, the four-sided element is divided into four triangles, as shown in Fig. 3. The area of the element can be obtained by the sum of the four triangles.

Coupled Fluid–Structure Interaction Model

Based on the above work, the interaction between the flow and fishing net can be simulated by dividing the net into many plane-net elements (see Fig. 4). The main concept of the numerical approach is to combine the porous-media fluid model and lumped-mass mechanical model to simulate the interaction between the flow and flexible nets (Bi et al. 2014a, b). Considering the example of a single flexible net, the calculation flow chart of the numerical approach is shown in Fig. 5. The details of the calculation procedure are as follows.

The calculation procedure includes four steps. Step 1 involves the simulation of the flow field around a vertical plane net without considering the net deformation using the porous-media fluid model. Step 2 involves the determination of the drag force and the configuration of a flexible net in a current using the lumped-mass mechanical model. The given initial flow velocity is the

Net Structures: Hydrodynamics, Fig. 4 Schematic of the net model

average value exported from the upstream surface of the plane net in the last step. In Step 3, according to the configuration of the net, the orientation and the porous coefficients of each plane-net element can be obtained, thereby determining the flow field around the fishing net. In Step 4, the drag force and configuration of the net are calculated again. The flow velocity acting on each lumped-mass point is the average value exported from the upstream surface of the corresponding plane-net element in the last step.

The terminal criterion of the calculation procedure is defined as $\Delta F = (F_{i+1} - F_i)/F_{i+1}$, where F_i and F_{i+1} are the drag forces of two adjacent calculations. If $\Delta F < 0.001$, the force acting on the fishing net is stable, and the configuration of the net is the equilibrium position considering the fluid–structure interaction. Thus, the calculation procedure is considered complete. Otherwise, the next iteration of the procedure is implemented, and Steps 3 and 4 are repeated until the criterion meets the precision requirement. Finally, the fluid–structure interaction problem can be solved, and the steady flow field around the fishing net can be obtained (see Fig. 6).

Other Related Studies

Hydrodynamics of the Net Element

To analyze the drag force on and the flow pattern around a cruciform element of the net structure, Bi

et al. (2017a) used computational fluid dynamics (CFD) to examine the drag effects and flow around T0 and T45 meshes oriented at angles of attack (AOAs) ranging from 90° to 0° (see Fig. 7). Two models were considered: (i) a one-cruciform element and (ii) a four-cruciform assembly composed of one element subjected to the wake effect of the upstream elements. The fluid flow around and drag of two cylindrical cruciform patterns, namely, a conventional (T0) pattern and a pattern rotated 45° in its own plane (T45), were numerically investigated by solving the three-dimensional Reynolds-averaged Navier–Stokes equations within the subcritical flow regime over AOAs ranging from 90° to 0° . First, the drag for the one-cruciform element was assessed. Next, the four-cruciform assembly (“square mesh”) was analyzed to consider the wake effect of tandem elements (see Fig. 8).

Effects of Biofouling on the Net Hydrodynamics

Biofouling is an inevitable problem in marine aquaculture that adversely influences the hydrodynamic behavior of the aquaculture facility (Bloecher et al. 2013; Gansel et al. 2017; Lader et al. 2015). In the study of Bi et al. (2018), the dominant biofouling on the netting of fish farms in the Yellow Sea of China was determined by field sampling (see Fig. 9). Plane nets with various levels of biofouling were obtained by submerging nets at different depths and for different durations.

Net Structures: Hydrodynamics, Fig. 5 Flow chart of the coupled fluid–structure interaction model. (Modified from Bi et al. 2014a)

The drag acting on biofouled nets in currents was investigated by conducting laboratory experiments. The results indicated that the drag acting on the net increases with increasing levels of biofouling. Compared to a clean net, the accumulation of biofouling can lead to more than 10 times the hydrodynamic load on the net (see Fig. 10).

The effect of biofouling on the hydrodynamic characteristics of the net cage is of particular interest, as biofouled nets can significantly reduce

the flow of well-oxygenated water reaching the stocked fish. The drag forces on and the flow fields around five plane nets with different levels of biofouling are calculated using the proposed model (Bi et al. 2015). Flow-through full-scale net cages with the same level of biofouling as the tested plane nets are modeled. The flow fields inside and around biofouled net cages are analyzed, and the drag force acting on a net cage is estimated using a control volume analysis

Net Structures: Hydrodynamics, Fig. 6 Flow-velocity distribution on the vertical plane $y = 0$ around the net calculated by performing a numerical simulation for the incoming velocity of 0.226 m/s: (a) considering the FSI between the flow and fishing net and (b) without considering the FSI (Bi et al. 2014a)

N

Net Structures: Hydrodynamics, Fig. 7 Definitions of the (a) angle of attack (AOA) and (b) T0 and T45 mesh orientations. The mesh orientation angle is the angle between the mesh axis and directional cosine of the flow vector on the fishing net

method. According to the numerical results, the empirical formulas of the reduction in the flow velocity and the load on the net cage are derived as a function of the drag coefficient of the corresponding biofouled netting.

To analyze the wave attenuation, the wave elevation both inside and around the cage arrays is numerically analyzed considering the effect of biofouling. According to the results of the present study, biofouling considerably influences the

Net Structures: Hydrodynamics, Fig. 8 Streamlines around T0 (left) and T45 (right) four-cruciform assemblies for discrete AOAs (Bi et al. 2017a)

wave elevation, and the damping effect of the cage array increases with increasing levels of biofouling. In addition, the incident angle of the waves has a significant effect on the wave field inside and around the cage array. From a wider perspective, the results of this study have implications for the transport of dissolved nutrients and hydrodynamic performance of the integrated multitrophic aquaculture configuration (Bi et al. 2017b).

Effects of Fish on the Net Hydrodynamics

A computational fluid dynamics study is performed to analyze the impact of cultured fish on the flow field through a net cage and the deformation of the net cage (Tang et al. 2017). The shear stress turbulent k- ω model is applied to simulate the flow field through the net cage, and the large deformation nonlinear structure model is adopted to conduct the structural analysis of the

Net Structures: Hydrodynamics, Fig. 9 Images of the biofouled nettings of net cages in a fish farm (Bi and Xu 2018)

Net Structures: Hydrodynamics, Fig. 10 Drag forces on nets with different levels of biofouling for various incoming velocities. Nets N0 to N5 represent the various levels of biofouling (Bi et al. 2018)

flexible net cage. A fish model is used to simulate the effect of the fish behavior on the flow pattern around the net cage and deformation of the net cage (see Fig. 11). In addition, the flow fields around the net cage in the current are investigated considering different fish group structures, fish swimming speeds, fish distributions, and fish stocking densities. The results indicate that the circular movement of fish in still water leads to a low-pressure zone at the center of the net cage, which causes a strong vertical flow along the centerline of the net cage. The drag force on the net cage significantly decreases as the fish stocking density increases; however, the most severe

deformation of the net cage occurs in the case of a medium fish stocking density.

Notably, a net cage is a type of floating structure anchored to the seafloor by mooring lines. The change in the flow field inside and around the net cage owing to swimming fish may further affect the hydrodynamic forces acting on the net cage (He et al. 2018). Recently, the effects of farmed fish on both the drag force acting on and the flow patterns inside and around the net cage were investigated experimentally by Bi et al. (2020). The laboratory experiments were conducted using a circular net-cage model with juvenile carp (*Cyprinus carpio*). The considered

Net Structures: Hydrodynamics, Fig. 11 Flow field around the net cage and net deformation in the case of different fish densities (Tang et al. 2017)

stocking density of the net cage ranged from 5.3 to 37.2 kg/m³ depending on the number of fish. Here, four net-cage configurations are designed for a laboratory experiment. The drag force acting on the net cage and flow velocities and the turbulence characteristics inside and downstream of the net cage are investigated. The results indicate that the biomass, flow speed, net-cage configuration, and net deformation have various effects on the drag force and fluid flow. Moreover, the potential influence of the fish size, swimming pattern of the fish school, and fish-net contact are also discussed.

The swimming pattern of the fish school is a key factor that influences the water inside and around the net cage. Fish schools swimming in an on-current pattern, similar to that in the present study, mainly change the flow pattern downstream of the net cage. However, certain fish tend to form a torus-shaped school and swim in a circular pattern (see Fig. 12). To maintain a circular pattern, the fish must accelerate toward the center of the net cage. This type of centripetal force is balanced

by the water volume outside the net cage, resulting in a change in the flow direction.

Key Applications

Global fish production has grown steadily in the last five decades, with the food fish supply increasing at an average annual rate of 3.2% and an increasing number of people relying on fisheries and aquaculture for food and as a source of income. The prediction tools for net hydrodynamics can be applied to enhance the energy efficiency of trawling and optimize the design of floating fish cages. Net hydrodynamics, such as the drag force acting on a net structure and the associated flow field, are of considerable interest over a wide range of practical applications, such as heat exchangers, damping screens, and various onshore and offshore structures.

The related outputs have broad application prospects in the development and utilization of

Net Structures: Hydrodynamics, Fig. 12 Circular swimming pattern of *Takifugu rubripes* in a square net cage. (Photo courtesy of Sheng-Cong Liu of Dalian Tianzheng Industrial Co., Ltd)

marine resources. This study can provide a new theoretical basis for the research, development, and design and safe operation of offshore aquaculture facilities, trawl nets, floating breakwaters, jacket platforms, and trash racks for coastal nuclear power plants, including net-structure components.

Definition

Shipping is a substantial emitter that accounts for about 3% of total global CO₂, 1–3% of SO_x, and more than 10% of NO_x (Bauhaug et al. 2009). Because of the strong growth of maritime transport sector in world trade, emissions from shipping are expected to increase 150–200% by 2050 (EC 2011). The effect of air emission of NO_x and SO_x from shipping on the environmental and health impact is widely realized and attracts a lot of critics from social public. The International Maritime Organization (IMO) has established regulations to reduce fuel consumption and air emission (EEDI, EEOI, SEEMP, ECA, etc. IMO (2013, 2014, 2016)). The inclusion of emission tax in the future bunker price will be likely implemented in the future shipping market (DNV 2011). According to the future fuel cost scenarios for the reduction of CO₂ and SO_x emissions by Eide et al. (2011) and DNV-GL (2014), the added premiums may push the bunker price up to 2000 USD/ton in 2040. Due to the increasing pressure on the uncertain bunker prices, stricter regulations on air emissions from shipping, as well as ambitious market plans to strengthen the branding, trade flexibly, and attract external stakeholders, the current shipping industry is putting great efforts and investment on technologies to improve ship energy efficiency and reduce fuel consumption and air emissions.

Overview of Technologies to Improve a Ship's Energy Efficiency

Many innovative technologies potentially aiming at reducing the fuel consumption and increasing a ship's energy efficiency have been investigated by various stakeholders and policy makers in the shipping industry, e.g., Bauhaug et al. (2009), Wärtsilä (2010), ABS (2015), DNV-GL (2014), etc. A detailed summary of those technologies is provided in Table 1, which categorize the technologies for new building and existing ships. It should be noted that simple summation of potential savings from all the listed technologies will greatly overestimate the benefits of

implementing multiple energy-efficient technologies for a given ship (Kesicki and Strachan 2011 and Kesicki and Ekin 2012). For example, considering the characteristics of operational profiles and structural configurations of ships in different segments, some of those technologies may be only efficient to certain types of ships. In addition, some technologies are mutually exclusive. According to an extensive market survey by DNV-GL (2014), shipping companies are more willing to implement mature and well-known technologies, and the most attractive technologies are those of little investment and easily realized benefits, for example, the slow-steaming, weather routing, energy performance monitoring system and voyage optimization, etc. It also indicates that for the current shipping companies, the biggest incentive to implement energy-efficient technologies is to be compliant with the regulation requirements, rather than the market-focused goals, such as strengthen market position and economic profits, etc. Part of the reason is that there is no transparent approach to evaluate the actual energy savings by implementing current technologies, while the indicated benefits are mainly claimed by technology providers' or manufacturers' data and analysis.

In general, new building vessels have already been optimized by ship design and construction companies to allow for the best operation performance. For the existing ships, any changes and installation of those energy efficiency technologies are often needed to be negotiated with shipyards and/or technology service providers and classification societies. These installations are often associated with quite large amount of investment cost to ship owners, while the energy savings due to the implementation of innovative energy efficiency technologies will eventually benefit most to the ship chartering companies. Most often, ship owners who pay for the extra installations might not benefit from the fuel saving made by these installed technologies. As is explained, some interest conflicts are often present regarding the cost of technology investments between different stakeholders of the shipping industry. These conflicts will also affect the investment wiliness for certain stakeholder to put

New Technologies in Auxiliary Propulsions, Table 1 Various energy efficiency measures used in the current shipping industry

Concept categorizes		Detailed measures	Potential savings (%)	Barriers
New building vessels	Hull form optimization and propeller configuration	Main dimension optimization, e.g., slender and larger ships, and less ballast water volume	4–9	Policy and regulation
		Ship energy system optimization based on actual planned operational profiles, fuel price, trade routes, loading conditions, etc.	3–5	Information and organization
		Optimization of stern bigle, rudder and propeller for inflow considerations (e.g., better skeg design, better propeller blade design)	3–4	Information, economic, organizational, and technical
		Optimization of hull shape and bulbous bow	2–5	Information and technical
		Better design with consideration of added resistance due to wind and waves in open sea	1–2	Technical and economic

		Trim, ballast and rudder control optimization, air lubrication	2–8	Technical and information
		Weather routing and voyage optimization	5–10	Information and technical

^aIt should be noted that the indicated energy savings from the listed technologies can differ significantly from various analysis approaches; therefore the intention of the table is to give a basic reference and relative saving potentials for different technologies

on the development and implementation of innovative energy efficiency technologies. Other barriers associated with the research and innovation of energy efficiency technologies will be further described in the next section. In the following, the definition and ideas behind various technologies listed in Table 1 will be briefly presented. More focus will be put on the technologies using wind power as auxiliary propulsion resources because of their big potential recognized in the shipping market.

Energy Efficiency Technologies from Ship Design/Construction Perspectives

For new building ships, the first measure to increase her energy efficiency is to optimize a ship's hull to minimize the ship resistance considering her life cycle service conditions. Often, a new ship construction starts with a standard hull form and propulsion system (that is often well optimized) provided by a shipyard. Then the hull form could be modified and further optimized to fulfill the ship owner's specific expectation on the ship's operational profile. The basis for a specific optimization is the ship's main particulars, such as ship dimensions and service speed. After a ship's main dimensions and operational conditions have been defined, more detailed hull optimization can be carried out from two different aspects, i.e., reduce resistance propulsion and increase propulsion efficiency. The hull optimization can be performed by designing better hull lines in particular for the design of forebody, afterbody, and appendages. The forebody optimization often needs to consider a ship's bulb design, waterline entrance, forward shoulder, and transition to the turn of the bilge. The afterbody optimization aims to reduce the added resistance due to the aft shoulder crest wave and the deep wave trough waves. It can also help to optimize the fluid flow entering the ship propeller and to avoid eddy effects, which can be used to improve the ship's propulsive efficiency. In addition, for certain types of ships of big superstructures, the wind resistances also play an important role in the hull optimization process.

Conventional hull optimization is often carried out for calm water sailing conditions, but an oceangoing ship seldom encounters sea conditions of no wind and waves during her service life. Currently, the computation capability has been increased dramatically; various computational hydrodynamic codes of different levels of difficulties have been developed to simulate/approximate a ship's energy performance in various operational and environmental conditions. With the computer aid for ship design, a typical new ship design and optimization process can involve four steps of analysis, from the basic empirical formula to the most advanced CFD (computational fluid dynamics) analysis as in the following Fig. 1 (Friendship 2018).

Optimization of Propeller Configuration to Increase Propulsion Efficiency

In addition to reduce a ship's resistance, the ship's propulsion system can also be optimized to increase her propulsion efficiency by configuring more proper propeller design suitable to the ship's actual operational conditions. For example, a conventional fixed pitch propeller is optimized to a ship's design speed and loading conditions when operated in calm water conditions with a specific engine RPM. Due to a ship's encountered sea environments, consideration of expected time of arrival, cargo safety, etc., a ship's speeds often vary a lot during her whole voyage. Therefore, the propeller is not always running on its design condition with the most optimum propulsive efficiency. To allow a ship's propeller to run their optimum setting for various operational conditions, a variable-pitch propeller (VPP) can be propulsive efficient for a wide range of engine RPM speeds for various encountering sea environment and load conditions. This is because the pitches of the propeller blades can be adjusted to transmit the highest effective power from a marine engine. For example, a ship requires more effective propulsive power to push the ship forward when she is fully loaded and encountering heavy sea conditions than she is sailing in light conditions (ballast in calm sea conditions).

New Technologies in Auxiliary Propulsions, Fig. 1 A typical hull form optimization process from Friendship 2017

Therefore, higher ship energy efficiency can be achieved by setting a ship's propeller blades to the optimal pitch. In general, the cost of a VPP is much more expensive than the FPP, but a ship installed with a VPP can accelerate, stop, and back faster, and it can also improve a ship's maneuverability by controlling the fluid flow onto the ship's rudder (Kasten 2018) (Fig. 2).

In order to increase a ship's propulsion efficiency, a lot of innovative ideas have been developed to change the fluid flow sucking into the propeller. For example, a device named as the inventor Grothues-Spork (1988) called Grothue's spoilers contains a set of fins installed on a ship's afterbody hull ahead of the propeller. The finds can help to straighten the flow right so that the flow could be redirected horizontally toward propeller (Fig. 3), and they may also help to avoid the flow separation, leading to an improved propulsion efficiency. Another similar idea is to put a big extra flow duct ahead of the propeller (Fig. 3 shows an example of the well-recognized Becker Mewis Duct for ship propulsion systems); it could also help to organize the water flow

entering toward the propeller. It has the potential to save up to 8% of fuel cost for certain ship types. Many other innovative ideas have been proposed to increase the propeller's work efficiency, from both the shape of propeller blade design, configuration of rudders, etc. A good summary can be referred to ABS (2015).

Lightweight Materials in Ship Constructions

From a ship's structural integrity perspectives, a ship should be constructed by enough materials to provide strength to overtake the forces caused by cargoes and environmental loads. Normally, the larger a ship is to be built, the more cargoes it is supposed to take, the more materials/steels (more lightweight) it will need to use to provide enough ship strength, and consequently, the more fuel is needed to consume for each voyage. One way to reduce a ship's lightweight, which will help to reduce the fuel consumption per transported cargo tonnage, is more lightweight

New Technologies in Auxiliary Propulsions, Fig. 2 A fixed pitch propeller (FPP) to the left and a variable-pitch propeller (VPP) to the right installed in ships

New Technologies in Auxiliary Propulsions, Fig. 3 Basic ideas of the Grothue's fins work principles (ABS 2015) and an example of a Becker Mewis Duct mounted ahead of a ship's propeller (Becker Mewis 2018)

materials such as composite materials, or high tensile steels that can provide the same strength as mild steel but needs less materials. As the increase of ship size, more and more percentages of HTS have been realized in today's ship construction. For large bulk carriers, the average of HTS usage has reached to 60%, while for

the large containers, it is about 55%, a bit less for the tankers. The usage of high tensile steel can save a ship's lightweight up to 12%.

Another big potential for a ship's lightweight reduction is to use the composite materials such as the fiber-reinforced plastic (FRP) or fiber glasses, which are actually widely used in small high-

speed craft and in the superstructures of certain ro-ro/ropax ships. The application of FRP for ship construction can help to reduce a ship's weight by 30–70%, contributing to significant fuel savings. However, the application of composite materials for a wide range of conventional ship construction is not so optimistic, due to construction cost, recycling cost, and fire safety in compared with the steel.

Energy Efficiency Technologies from Ship Operation Perspectives

In comparison with the new building ships, which have already been quite well optimized to follow the environmental regulations on energy efficiency, it is rather an urgent demand to develop energy efficiency technologies for existing ships. In addition to install some extra equipment as the previous subsection to increase a ship's propulsion efficiency, more straightforward and efficient way is to develop technologies or management/maintenance strategies to assist a ship's operation.

Machinery Maintenance and Update Plan

A ship's fuel is directly consumed by a ship's complex machinery system, in which a lot of improvement could be achieved by better planning, optimized control, and configuration setting. For example, in addition to the energy used to provide propulsion force to move a ship forward, a lot of energy onboard a ship is actually used to provide electric power, such as heating the oil tank for chemical ships, powering the air conditions to containership and passenger ships, etc. The electric power onboard ships can be provided by either a generator attached to the main propulsion engine or by generators driven by independent diesel engines. To have an optimum setting/selection of engine generator, careful consideration should be made toward a ship's actual operational conditions and engine power usage. Normally, for ships with constant electric power requirements, i.e., during both sailing and anchor conditions, an auxiliary diesel engine generator is a more suitable option. While sometimes, the

mixture usage of diesel engine generator and generator mounted on a ship's main engine can provide even higher efficient operation through an optimal power management plan.

There are often many valves/pumps in a ship's machinery systems to control the bunker flow into the ship's main engine. The pump systems are often controlled by electronically controlled engines. In the shipping market, some companies also use the computer-aided management system to automatically adjust the work frequency of the pumps according to specific loading and operational and environmental conditions. Those electronically controlled engines and turbo-charger control equipment connected with a ship's main engine can use low-speed diesel engines because low to medium load engines are often more energy efficient. This kind of choice will be significantly energy efficiency beneficial in particular for operating consistently at lower speed/loading conditions than the design service or heavy sea operation conditions.

Waste Heat Recover System

Large heat energy is generated by a ship's machinery system, in particular when running with full load and heavy weather conditions. For example, normally, about 5% of a ship's marine engine consumed energy/fuel is used for engine cooling system, and another 25% is simply emitted as exhaust gas such as CO₂. A waste heat recovery system is an energy recovery heat exchanger that transmits heat contained at exhausted gas at high temperature to other parts that can absorb or utilize the heat energy for their purposes to increase a ship's total energy efficiency. One traditional usage of this heat energy is, for example, to generate fresh water and steam for heating onboard ships. Currently, due to the increase of ship size leading to larger installed marine engine, it means that the exhausted gas (heat energy) contains much more energy than it can be used for fresh water and heating. Modern waste heat recovery systems in the market can be used to transfer the heat energy to generate additional steam to power a steam turbine, which can directly add mechanical force on the engine shaft to provide propulsion forces to ships.

Ship Performance Monitoring System

In order to optimize a ship's energy consumption, one of the key elements is to understand the ship's actual performance, which can be used to identify possible solutions/technologies to increase her current performance during the operation. Now a lot of companies are providing service to record, collect, monitor, and analyze a ship's performance in real time, such as the Marorka and Kongsberg systems. By continuously monitoring and analyzing a ship's performance, it cannot just help onboard crews become aware the importance to operate the ship in a more energy efficiency manner and understand the outcome of performance change caused by both internal and external factors but also provide background/evidence for fleet management team to plan a company ship energy-efficient management plan. Among other parameters, some fundamental parameters will be monitored by the system, for example, fuel consumption rate (per hour/nautical mile), specific fuel oil consumption (SFOC), ship speed, shaft power, shaft torque, RPM, etc. Another important parameter to be monitored is the so-called weather impact, i.e., how much extra energy consumption caused due to the encountered sea environment. In addition, many other important parameters related to the machinery system, environmental parameters (wind, wave, currents), and operational parameters (position, heading) are also collected in the system. A visualization platform is also integrated in the system to demonstrate a ship's performance in nearly real time. Meanwhile, some

low resolution of postprocessing data will be sent back to the ship's traffic management office through satellite.

In a ship's performance monitoring system, the most important component is to build the accurate baseline, which describes a ship's energy consumption in ideal conditions, i.e., sailing in calm water conditions with a newly maintenance hull and machinery system for various loading and operational (sailing speeds) conditions. Based on the baseline constructed in the system, the fleet management team could determine the ship's maintenance plan to increase the ship's energy efficiency. For example, when a ship is launched into the water, the microorganisms, plants, algae, or animals will continuously accumulate on the ship's wetted surfaces caused the so-called biofouling (Fig. 4), which can increase a ship's weight and thus the resistance significantly. If the biofouling occurs at the ship's propellers, it will reduce a ship's propulsion efficiency. Both can lead to large extra fuel consumption. In addition to every 5 years' dry dock maintenance, most shipping companies make other extra hull/propeller cleaning schedules to increase their ships' energy efficiency. The most optimal cleaning strategy is based on the performance analysis from a ship's monitoring systems.

In addition, the performance monitoring systems are often used to evaluate benefits of the implementation of easily plug-in energy efficiency solutions, such as the well-recognized weather routing and slow steaming. The weather

N

New Technologies in Auxiliary Propulsions, Fig. 4 Biofouling on a ship's hull (left) and on a ship's propellers (middle and right)

routing service is a computer-aided navigation system, which helps to plan a ship's sailing course and speed according to received weather forecast along the ship's sailing area. Often, due to large uncertainties of weather forecast especially after 2–3 days, the planned routes may not be very reliable. Furthermore, there are many weather routing services provided in the market. Therefore, the evaluation from a ship's performance monitoring system becomes an important source helping to select reliable energy efficiency technologies.

Renewable Energy Devices

The ocean contains huge amount of clean and renewable energies, such as the wind, tidal, and solar energy. Reliable technologies to harvest those renewable energy can significantly increase a ship's energy consumption. Through weather routing systems and training experiences, master mariners are making use of ocean currents (or avoid if sailing against ocean currents) to navigate their ships to save fuel burning. Furthermore, owing to the large deck space of merchant ships, such as tankers and bulk carriers, many innovative solutions have been proposed to install solar panels on board ships to harvest solar energy for providing electric power or even propulsion to ships. Concerning the whole sailing history, human beings have long history to make use of wind energy for ship propulsion. The wind power is also recognized as one of the most prominent renewable energy sources that can be realized by modern ships to reduce fossil fuel burning and air emission from shipping. In the following, we will focus on the description of wind propulsion concepts for ship navigation.

Wind Power as Auxiliary Propulsion in Ships

In the history of maritime industry, merchant ships using hybrid propulsions between steam engine and traditional sails have experienced about one century. Eventually, by the early 1900s, shipping companies migrated their ships to steamships. Gradually every transoceanic sailing, ship company went out of business. This is because of the

high energy efficiency of marine engine combined with modern propeller design and the low cost of energy sources. Furthermore, merchant ships with steam/marine engine are capable to sail across oceans faster than the wind and can be operated in a more regular and flexible manner. Figure 5 presents some of the most common discussed wind assistance ship using wind power as auxiliary propulsions. The state-of-the-art research and feasibility of these wind assistance ship concepts during the 1980s were extensively reviewed by, e.g., Nance (1985) and Bergeson and Greenwald (1985).

Wind Sail Concepts

Currently, hybrid ships using sails as auxiliary propulsion have attracted a lot of attention. Sails mounted on masts are often categorized as traditional soft sails and wingsails, which are airfoil-like structures similar to airplane wings. Traditional soft sails are still used for primary propulsion to many commercial fishing crafts in developing countries. These sails are also used on larger trading vessels in trade areas such as South Pacific routes with long distance and high fuel costs (Teeter and Cleary 2014). Soft sails are often designed as fore-and-aft sails or square sails, and one big advantage of using soft sails on merchant ships is their relative cheap investment for installation and maintenance. However, their drawbacks are also quite obvious, for example, lack of auto operation/control of the soft sails; it has to either rely on extra crew members to pilot sails or use very complex and expensive automate system for launch, recovery, and operation of the sails. Furthermore, the fuel savings using soft sails are usually very low in addition to the difficult handling problems (Schenzle 1985). Figure 6 lists a few wingsail design proposals in the early 1980s (Nance 1985). The most successfully implemented concept is the folding wingsail developed by the Japanese company NKK and fitted first to the *Shin Aitoku Maru*, a 1400 DWT tanker (Watanabe et al. 1982). Right after the successful installation of the system onboard the *Shin Aitoku Maru* tanker, it has also been retrofitted to about 10 ships of different sizes from 600 to 31,000 t, built in

New Technologies in Auxiliary Propulsions,

New Technologies in Auxiliary Propulsions, Fig. 6 Typical wingsail proposals developed in the early 1980s (Nance 1985)

6 different shipyards and operated by 6 different companies in Japan. This system has been demonstrated with a potential fuel saving up to 20–30%.

The Flettner Rotor Ship Concept

The Flettner rotor ship concept makes use of Magnus effect to generate propulsive force from the airflow around rotating cylinders. As is

New Technologies in Auxiliary Propulsions, Fig. 7 A sketch of Magnus effect for a Flettner rotor ship with vertical rotating cylinder

Fig. 7, assume that a ship is heading to the left, and the wind is blowing to the up direction. To generate propulsion force to the left, the cylinder must be rotated clockwise. The rotating cylinder will cause fractional drag force on the surrounding airflows, leading to that the speed of the airflow in front of the cylinder is greater than that behind. Based on the Bernoulli equation, it can cause lower air pressure in front of the cylinder and generate lift force on the cylinder to push the ship forward.

The first system to prove the Magnus effect concept that can provide auxiliary propulsion to ships was designed by German engineer Anton Flettner. The demonstration project was carried out on a schooner (the Buckau), which was outfitted with cylindrically shaped, rotating masts of 15 m tall and 3 m in diameter and crossed the North Sea from Danzig to Scotland in February 1925. In the past century, the Flettner rotor ship concept was never taken hold in the commercial shipping market due to its less competitive capabilities in comparison with steam and diesel engines as ship propulsions, even though the concepts were shortly revisited in the 1980s by maritime academia and research institutions driven by the concerns of the oil crisis (Nance 1985; Bergeson and Greenwald 1985). Flettner's cylindrical rotors were further with discs distributed along the cylinder. The performance of cylinder rotors with and without discs for ship auxiliary propulsion was experimentally studied by Clayton (1985). But the cylinder with discs distributed concept was abandoned by the inventor Thom since the power required to

spin the rotor with large discs became too expensive.

Due to the large weight and high central gravity of the rotors, a ship's structural integrity in some local details, as well as the vessel's hydrostatic and seakeeping capability, should be carefully planned and analyzed to ensure the safety. After 10 years' technical development, the first modern vessel, i.e., the 10, 000 dwt cargo vessel E-Ship 1 (ENERCON 2013) was completed and launched in 2010. She was equipped with four Flettner rotors of 27 m height and 4 m in diameter, demonstrating the design feasibility of the technology (Fig. 7).

Towing Kites Concepts

The concept of utilizing wind force from towing kites to provide propulsion forces to ships has been systematically invented since the 1980s (Duckworth 1985; Wellicome and Wilkinson 1984). Similar as other wind-assisted ship propulsion concepts, the incentive for the development of towing kite propulsions is also originated from the financial reasons and environmental concerns of bunker fuel consumption in shipping. Schlaak et al. (2009) investigated the worldwide shipping market for the implementation of wind towing kites as auxiliary ship propulsions. Based on the same result database from field trials with a kite into a study, it concludes that kite systems could be retrofitted to around 60,000 out of a total 90,000 ships. Significant fuel saving potential has been presented for a multipurpose freighter, between 1% and 21% for a ship speed of 15 knots

New Technologies in Auxiliary Propulsions, Fig. 8 A SkySails towing kite implemented in oceangoing commercial vessel (left), another kite propulsion concept developed by Kiteship (right). (Courtesy from the Internet)

and between 4% and 36% for a ship speed of 13 knots.

Before practical installation of kite systems in ships, two technical problems have to be solved. The first is a reliable prediction of mechanical performance of auxiliary wind propulsion using kites, and the other is the kite control/operation system, as well as the effect of ship structural and stability due to the installation and an optimum ship route plan system, which is required for all the wind-assisted propulsion concepts. The principle of ship propulsion using sails assumes that the aerodynamic forces are larger than kite masses, leading to the fact that the acceleration effects could be neglected. Thus, the whole kite system can be considered to be in equilibrium flight state. In addition, the kite operation system for auxiliary ship propulsion has also been investigated. For example, Grosan and Dinu (2010) studied the influence of a ship's stability and maneuverability with zero forward speed under certain wind conditions, Wrage (2007) patented his technical achievement for the kite launch and recovery systems, and Erhard and Struch (2012) presented their research efforts for an auto-pilot kite control, etc. These technical developments have enabled kite systems to be installed commercially for transoceanic voyages. It has been becoming the most popular wind-assisted ship propulsion concepts in the current shipping market due to its technical maturity. The industry partner SkySails GmbH is the market and technology leader in the field of marine towing kite

systems. SkySails kites are the key technology for capturing the vast potential of high-altitude winds, and SkySails is the first company in the world that has succeeded in developing towing kite technology into an industrial application. Figure 8 presents a prototype of SkySails towing kite implemented in oceangoing commercial vessel. The latest product generation developed by the company can replace up to 2 MW of the main engine's propulsion power. While another successful market player on the kite-assisted ship propulsion uses the system of different size and shape of kites developed by KiteShip (Kiteship 2018), which has a successful track record of using kites to provide propulsion force to pleasure yachts. They also built the world's largest sailing kite in 1997 and recently applied their systems to auxilarily power oceangoing tankers.

Other Wind Propulsion Concepts

Another more challenging concept is to install one or several wind mills onboard a ship. This concept can not only use the propulsion provided by windmills but also use the electrical power generated by windmills. Since wind mill propulsion generally provides high propulsive force only when the ship speed is less than about half the wind speed (Blackford 1985). This implies that for wind turbine propulsion to be the preferred for slow-steaming ships or sailing in high wind conditions. But the high wind conditions may induce extra challenges to a ship's structural safety and its stability in open sea operations. Ship motions

when operated in the open sea can significantly decrease the efficiency of the power generations from onboard windmills. Furthermore, to use the electrical power generated by the retrofitted windmills, large amount of investment must be put to revise marine engine system in ships. Moreover, maintenance cost may become too expensive during the operation period of windmills because of their working conditions under moist and salty sea environments. Hence, there are no merchant ships equipped with windmills to provide auxiliary ship propulsions (Böckmann and Steen 2011).

Scientific Fundamentals

The History of Nonexplosive Removal

Subsea systems are capable of producing hydrocarbons from reservoirs in all water depths and are frequently used to develop deepwater marginal fields. Deepwater subsea wells account for 164 of the 295 subsea wells in the Gulf of Mexico (GOM) (Baud et al. 2002). Compliant towers, spars, tensionless platforms, and floating production units (Fig. 1) are also employed in the deep water (Mark and Robert 2005).

The decommissioning of offshore structures, respecting the end of the production life, is a severing intensive operation (MMS 2004). Cutting is often required throughout the structure above and below the waterline and mudline on braces, pipelines, risers, umbilicals, manifolds, templates, guideposts, chains, deck equipment, and modules. More significant cutting operations are required on elements that are driven into the seafloor, such as multi-string conductors, piling, skirt piling, and stubs which need to be cut at a minimum of 15 below the mudline, pulled, and removed from the seabed.

A variety of technology exists to perform severance operations. These include abrasive water jet, diamond wire, diver torch, explosives, and mechanical and sand cutters. For severing operations that occur above the waterline, the cutting technique selected is usually dictated by the potential for an explosion. Cold cut methods are used when the potential for an explosion exists; otherwise hot cuts are employed. Cutting in the air zone is conventional since it involves methods which are regularly used for dismantling onshore industrial facilities. Below the waterline cutting is more specialized. In water depths that do not exceed 150 ft or so, divers perform cuts on simple elements such as braces and pipeline, and for shallow water structures such as caissons, torch cutting is sometimes the preferred severance method. Divers are also used to cut when other techniques produce an incomplete cut. In water depths exceeding 150 ft, remotely operated vehicles and automated diving systems are deployed with abrasive and diamond wire cutters and explosive charges. Major cutting operations

Nonexplosive Removal, Fig. 1 Deepwater development

on conductors, piling, and stubs normally employ mechanical, abrasive water jet, and explosive charges. Mechanical and explosive methods are primarily used for conductors with abrasive water jet and explosives predominately used for pile severance. The decision to use explosive and/or nonexplosive methods depends on the outcome of a risk-based comparative assessment involving cost, safety, technical, environmental, and operational considerations. The purpose of this report is to describe the factors involved in the decision to use explosive or nonexplosive methods: the business, market, and contract environment of nonexplosive technology and the environmental, physical, safety, and activity requirements associated with nonexplosive methods.

The Science and Technology of Nonexplosive Removal Methods

The science and technology of nonexplosive removal methods has changed remarkably, although significant progress has been made in diamond wire and AWJ (abrasive water jet) technology. For the most part, the resources required in decommissioning involve standard, readily available technology and tools which have been available for some time. There has been only incremental technological advancement associated with cutting technology over the past

decade, or indeed, over the past half century. Mechanical pipe cutters and diver torches are roughly the same today as they were 10 years ago, and while AWJ and diamond wire applications continue to see an increase in the frequency of application, a variety of factors continues to limit their application in practice. Nevertheless, while the routine application of diamond wire methods is still several years away, the technology has made significant strides. Further, the physical limitations associated with AWJ systems (e.g., water depth, cost, reliability) are significantly better than they were a decade ago, due to the steady influx of new contractors into the GOM and their product development.

Mechanical Methods

Cutting mechanisms that use hydraulically actuated, carbide-tipped tungsten blades to mill through tubular structures are called mechanical cutters. Figure 2 shows a schematic of this type of system. The mechanical casing cutter is perhaps the oldest method for cutting well conductors. The casing cutter is deployed on a drill pipe string, and the cutting tool has three blades which fold up against the drill pipe. The tool is lowered into an open pile or well using a drill rig. When hydraulic pressure is applied to the tool, the blades are forced outward as the tool is rotated by a power swivel. The carbide-tipped blades cut through the strings of the well, while centralizers on the tool keep it concentric inside the tubular

Nonexplosive Removal, Fig. 2 Schematic of a mechanical cutting system (MMS 2004)

member. Drillers watch the back pressure on the drill water to determine when the cut is complete, and cut verification can be made after the tool is recovered by the marks of penetration of the blades (Manago and Williamson 1997).

Mechanical cutters are frequently used for cutting shallow-water, small-diameter caissons with individual wells and well protector platforms with vertical piles (Fanguy 2001; Pulsipher 1996). Mechanical cutting is rarely used in conjunction with a derrick barge spread since the operation is time-consuming and inefficient and rig-up and rig-down time may be considerable. After wells are plugged and casing tubing cut and pulled, the contractor may run a mechanical cutting tool (or sand cutter) downhole to cut the conductors or, depending on the preference of the operator and configuration of the platform, may

subcontract for abrasive water jet or explosive severance methods.

To cut piling with mechanical cutters, the piling must be open at the surface to accommodate the power swivel. Thus, the deck of the platform must be removed prior to the operation using a derrick barge, and after the deck is removed, it is highly unlikely for a barge to stay on-site when the mechanical cutters operate. Remobilizing a derrick barge, however, is usually not an option and would represent a significant cost increase in the operation. Mechanical cutting is therefore rarely used for piling.

Abrasive Methods

Abrasive cutters are the mechanisms that inject cutting materials into a water jet and abrasively wear away steel/concrete. Abrasive technology has a long history of application in industrial and manufacturing processes and has been used in shipyards for many years. Several different systems of abrasive cutters exist.

Abrasive cutters can be classified as:

1. Low-pressure/high-volume systems (sand cutting)
2. High-pressure/low-volume systems (AWJ)

Cutters that use sand or slag mixed with water at low pressure (4000–10,000 psi) and high volume (80–100 gal/min) are called sand cutters, while cutters that use garnet injected at the nozzle at high pressure (50,000–70,000 psi) and low volume (50–80 gal/min) are commonly referred to as abrasive jet cutters (NRC 1986). The abrasive provides the force for cutting and is introduced at the cutting nozzle and sent down a hose with air pressure or through a water-based solution. Abrasive jet cutters produce a jet of water mixed with garnet under high pressure and directed through a diamond orifice. Abrasive jet cutters can cut both internal to the tubular member as well as external to the member, although internal cutting is the preferred method if below mudline access to the foundation pile can be achieved. The minimum inside diameter that can be accessed with abrasive cutters is approximately 7 in. and beyond 200–250 ft. Figure 3a and b

Nonexplosive Removal,

Fig. 3 Tool of abrasive cutters: (a) the abrasive water jet cutting tool for piles or caissons; (b) the cutting tool intended for use in conductors or small piles

shows the abrasive water jet cutting tool for piles or caissons and the cutting tool intended for use in conductors or small piles, respectively.

There also exists the problem of verifying that the cut has been made when using an internal abrasive cutter. Unlike explosives, the conductor or pile often does not drop, confirming that the cut was successful. With an abrasive tool, the width of the cut is small, and when combined with the soil friction, a visual response generally does not occur. To verify the cut, the conductor is pulled with either the platform crane or hydraulic jacks, and the lift force must overcome the conductor weight and the soil friction.

Diamond Wire Methods

A diamond wire cutting system uses a diamond embedded wire on a chain sawlike mechanism to cut steel, concrete, or composite material above and below the waterline. The wire is veered onto hydraulically driven pulleys resembling a band saw and mounted on a frame. The system can be configured to cut virtually any structural component, caissons, conductors, risers, and pipelines and is not limited by size or material as long as the cutting tool can be attached to the member. Figures 4 and 5 show diamond wire cutting tools for different applications. Figure 6 shows a close-up view of the cutting wire and industrial diamond beads.

The cutting machine is hydraulically clamped or manually strapped to the structure, and a surface-activated motor activates the tool. The diamond wire is driven at high speeds, and depending on the material and thickness, wire speeds are maintained to produce the cut. Even under large axial compressive loads, tubular members can be cut with diamond wire, and one of its strengths lies in its ability to cut large wall section thickness (Brandon et al. 2000). The operator monitors the progression of the cut and makes adjustments to improve the efficiency of the machine.

Diver Torch Methods

Underwater diver cutting is virtually the same as land-based cutting, but the torch used is somewhat different. In underwater arc cutting, an outside jet of oxygen and compressed air is needed to keep the water from the vicinity of the metal being cut. A tube around the torch tip uses air and gas pressure to create a gas pocket. This will induce an extremely high rate of heat at the work area since water dispels heat much faster than air. Underwater cutting can also be accomplished with an oxyhydrogen torch. Hydrogen is typically used instead of acetylene because of the greater pressure required in making cuts at increased depths.

In shallow water and for simple structures such as caissons, diving is sometimes the preferred

cutting

N

method. In deep water, because of the physical limitations associated with diving, an ROV or ADS system is commonly used in conjunction with a cutting torch. Diver cuts usually cost far more than other cutting technology, and the risk involved to the diver – especially in deep water – makes torch cutting generally less attractive than other removal options.

Key Applications

Environmental and Physical Impact

Energy is required to do work and all cutting operations require the expenditure of energy. As work is performed, energy is transferred and transformed which may have some impact on the ocean environment where these operations are

Nonexplosive Removal, Fig. 6 Local detail of the diamond wire, showing industrial diamond beads and spacers

performed. The power requirements of a cutting spread are approximately the same as a small offshore fishing vessel (less than 200 horsepower, or 150 kW). Unlike a typical sport fishing vessel, the typical cutting spread is fully self-contained with no marine discharges, other than the jet in the case of AWJ systems. Nonexplosive cutting methods are considered to be ecological and environmentally sensitive severance methods. For that reason, environmental and physical impact data of nonexplosive techniques are quite limited in the academic and trade literature. No record of negative environmental impacts for nonexplosive cutting methods has been found in the literature. In mechanical, AWJ, and diamond wire removals, diesel-fueled mechanical systems are employed in the operation which results in vibrations, the emissions of CO₂ and other gases to the atmosphere, and, potentially, low-frequency sound waves into the ocean environment. Abrasive water jet cutting involves using seawater and garnet or copper slag (grit). There is the question of the impact of the fluid and grit on the marine environment. Since the fluid involved in abrasive cutting is seawater and the grit is essentially inert, the environmental impact is believed to be inconsequential. Garnet is an inert rock material that poses no environmental consequences that have been reported. The level of available copper present in the slag is very low, and there are currently no restrictions on its use or reported environmental issues. The

noise level of the supersonic cutting jet is safe for divers and is not considered harmful to marine life. Mechanical, abrasive water jet and diamond wire methods are generally considered harmless to marine life and the environment. No adverse environmental impacts related to any of these cutting methods have been reported in the literature. The direct products of the processes are water, metal cuttings, and abrasive grit particles. Therefore, we conclude that there are no adverse environmental impacts associated with any of the nonexplosive cutting methods.

Nonexplosive Removal Market Potential

Mark and Robert (2005) did an estimation of the size and potential value of the nonexplosive severance market in the GOM. They assumed an average number of piles and conductors that need to be removed per structure type so that the total number of cuts can be estimated. Each caisson is assumed to be composed of one conductor, each well protector three piles and one conductor, and each fixed platform six piles and four conductors. In terms of the total number of tubular elements that are expected to be cut, the expected values $E(N_p)$ and $E(N_c)$ for the number of piles and conductors associated with each structure class were obtained. In their research, the value of the nonexplosive removal market in the Gulf of Mexico is estimated to range between \$1.5 M and \$2.5 M/year. The manner in which the nonexplosive removal market is “shared” among the subcontractors depends on the type of cuts that need to be made as well as the reputation, sales, performance, quality, and cost of the subcontractors providing the service. The final assumption decomposes the severance market according to mechanical/sand cutters, AWJ, and diver torch operations. The decomposition is a subjective assessment used to divide the market according to method of severance. Severing caissons with nonexplosive methods is assumed to be divided equally among mechanical/sand cutters, AWJ, and diving subcontractors. The split for well protectors and fixed platforms is assumed to be 60:40 and 80:20, respectively, relative to AWJ and mechanical cutting. In addition, changes in the

number of structure removals will impact the valuation estimate.

Definition

*Sloping
Structure*

Offshore structure/ships with a sloping surface, which promotes the flexural failure of sea ice.

Broken Ice

Broken ice is loose ice, which consists of small floes that are broken up as a result of natural processes or active or passive intervention (ISO19906 [2019](#)).

Floe Ice

An ice field consists of ice floes of various sizes. The ice floes can be as large (in the order of kilometers) as being considered as level ice and as small (in the order of meters) as being considered as rubble ice (Lu [2014](#)). This is more general concept and includes

<i>Ice Fracture Simulation</i>	both the conventionally discussed “level ice” and “broken ice” conditions. From a numerical simulation point of view, this represents the simulation process to describe ice bodies changing from a continuum into fragments.
<i>Ice Rubble Transportation Simulation</i>	From a numerical simulation point of view, this is to simulate a collection of ice blocks interacting with each other and the structure; the ice blocks (ice rubble) normally slide along the ship hull or accumulate around the structure leading a significant amount of ice load on the structure.

Scientific Fundamentals

During the ice–structure interaction process, in most cases, the ice fractures first; then the ice fragments shall accumulate around the structure and need to be transported around the structure. Different interaction phases have been identified for this process for level ice–sloping structure interactions. These are:

- The ice breaking phase
- The ice rotating phase
- The ice rubble transport phase

For the ice breaking phase, there are many failure modes that can be identified depending on the ice feature, interaction velocity, and contact properties. The following theoretical simplifications can be made based on field observations:

- For level ice interacting with a sloping structure, it is mainly the local out-of-plane flexural type failures (Lu et al. 2015b) that are taking place.
- For floe ice, which is a more general term, the ice fails in both the local out-of-plane flexural

type failures and the in-plane splitting failure (Lu et al. 2015a); and the competition between these two types of failure should be accounted for (Lu et al. 2016a).

For the ice rotating phase and the ice rubble transport phase, we are essentially facing a multi-body dynamic simulation problem, that is, how an ensemble of ice blocks interacts with each other and the structure needs to be simulated.

Simulation Methods

The above two simulation tasks (i.e., ice fracture and ice rubble transport) can be solved with existing computational fracture mechanics and discrete element methods, respectively. Given the different physical natures of the processes that are to be simulated, different numerical simulation methods can be applied. Generally speaking, three categories of method can be identified. These are:

- Empirical formula-based simulation
- Hybrid approach
- Purely computational approach

Empirical Formula-Based Simulation

The empirical formula-based simulation is essentially a so-called “edge-tracking simulator” (Keijndener 2019). These simulations utilized empirical formula to calculate the ice fracturing (i.e., ice crushing and ice bending) and then utilize, for example, Lindqvist formula (Eq. 1), to calculate the ice rotating and rubble transport component.

$$\begin{aligned}
 R_s = & (\rho_w - \rho_i)ghB \left[T \frac{B+T}{B+2T} \right. \\
 & + \mu_{is} \left(0.7L - \frac{T}{\tan \phi} - 0.25 \frac{B}{\tan \alpha} \right. \\
 & \left. \left. + T \cos \psi \cos \phi \sqrt{\frac{1}{\sin^2 \phi} + \frac{1}{\tan^2 \alpha}} \right) \right] \quad (1)
 \end{aligned}$$

where

ρ_w and ρ_i	are the water and ice density.
h	is the ice thickness.
B, T, L	are the ship beam width, draft, and length.
$\psi = \arctan(\tan \phi / \sin \alpha)$	calculated from the stem angle ϕ and water entry angle α .
g	is the gravitational acceleration.

When applying the empirical formula, for example, to calculate the ice bending failure, the ice edge has to be constantly tracked and updated numerically, such that the ice–structure contact region can be identified.

When utilizing Eq. (1), it is implicitly assumed that 70% of the ship bottom shall be covered by ice rubbles (Lindqvist 1989). This leads to the coefficient 0.7 in the second term of the formula.

This method is rather simplified in terms of the ice fracturing and rubble accumulation terms; in addition, this method is mainly suitable for level ice–sloping structure interactions. The major challenge is to numerically track the ice edge to apply empirical ice breaking formulas. Extensive work has been carried out within this category. One can refer to work conducted in relevant literatures for detail (Su et al. 2010a, b, c, 2011; Tan et al. 2013; Zhou et al. 2011).

Hybrid Approaches

Computational Ice Fracture with Empirical Rubble Transport Formulations

Given the different interaction phases that are involved, one can choose different methods to simulate different phases and then combine them. For example, Valanto (2001) formulated the ice plate bending problem with consideration of the fluid beneath ice using potential theory. This is a rather computationally intensive approach to characterize the ice fracture part. However, when it comes to the rubble transport, Valanto (2001) simply adopted Eq. (1) to calculate the rubble transport. In this regard, extensive researches have been carried out on solving the ice fracturing part computationally; and in a

similar fashion, this load component can add up to the rubble transport part using the simplified Eq. (1) to calculate the total ice resistance. For example, Sawamura et al. (2008, 2010) numerically tabulated the results of an infinite ice wedge’s flexural failure, which were used for level ice–ship interaction simulations. The bending failure of an ice wedge is of major concern in this regard. There are many methods available to study the bending failure of an ice wedge; here we will present the cohesive zone method computational fracture mechanics.

The bending failure is controlled by circumferential crack initiation. Therefore, a strength-based theory would serve the purpose. However, it is possible to follow a fracture-mechanic approach to simulate the complete circumferential crack initiation and propagation process. There are many numerical methods available for this. Lu et al. (2012) presented the cohesive zone method based “element erosion method” (see Fig. 1a), “cohesive element method” (see Fig. 1b), “discrete element method” (see Fig. 1c), and “extended finite element method” (see Fig. 1d) to simulate a single flexural bending process. The simulated ice bending failure results can be tabulated and combine with existing rubble transport empirical formulas to calculate the total ice resistance.

Analytical Ice Fracture with Computational Rubble Transport Formulations

Another hybrid approach is to calculate the ice fracture with analytical ice fracture solutions while simulate the rubble transport with Discrete Element Method. This work has been extensive developed and carried out in a series of recent studies (Lubbad et al. 2018a, b; Raza et al. 2019; Tsarau et al. 2018). The idea is to identify the most often observed failure modes of an ice floe and solve them by analytical solutions.

To achieve an analytical solution-based ice fracture calculation framework, the interaction mechanism between a floe ice and a floating structure can be simplified in Fig. 2 together with related contact forces. The two types of failure modes, that is, out-of-plane flexural failure by

Numerical Simulation Floe Ice–Sloping Structure Interactions, Fig. 1 Different numerical scheme to simulate the bending failure, by Lu et al. (2012)

Numerical Simulation Floe Ice–Sloping Structure Interactions, Fig. 2 Simplified interaction mechanism to with contact force components

the vertical force F_Z and the in-plane splitting failure force by the horizontal “wedge-out” force F_Y are considered separately in the following:

The vertical direction contact force F_Z , which leads to the out-of-plane bending failure, and the horizontal “wedge-out” force term F_Y , which leads to the global splitting failure, can both be formulated analytically (see the chapter on ► “Sloping Structure: Floe Ice Interactions”).

Combining the analytical solution in a DEM based simulation environment to simulate the rubble transport, the entire ice–structure interaction process can be simulated. The above analytical fracture based algorithms are implemented in the Simulator for Arctic Marine Structures (SAMS), which is a multibody dynamic based simulation tool (Lubbad et al. 2018a). A sample simulation snapshot is illustrated in Fig. 3. The top view in Fig. 3a shows the ice fracturing processes (both bending and splitting failure of ice floes) which are governed by analytical solutions; the underwater view in Fig. 3b shows how the broken ice rubble is sliding around the structure. The analytical fracture-based hybrid approach is rather efficient in terms of simulation. It can simulate an unprecedentedly large, special, and temporal domain, such that complicated Arctic operations, such as Ice management, which spans several kilometers and lasts for several hours can be

efficiently simulated by this hybrid approach (Lu et al. 2018b).

Purely Computational Approach

There exist many computational methods that can simulate both the fracture and upcoming fragmentation of ice floes in one goal. From a computational fracture mechanics point of view, Ingraffea and Wawrzynek (2004) made a classification and detailed review of all possible numerical methods. Here we will limit ourselves and selectively present the numerical methods that have been utilized in ice engineering; and the focus will be on ice–structure interactions.

Combined Finite Element and Discrete Element Method

Before the ice fractures, finite element method is utilized to calculate the stress and displacement fields within the sea. When fracture takes place and results in ice fragments, the discrete element method is utilized to simulate the ice fragments. This method has been extensively studied and developed over the years by the research group in Finland (Paavilainen and Tuhkuri 2012, 2013; Paavilainen et al. 2006, 2009, 2010, 2011; Ranta et al. 2017; Tuhkuri and Polojärvi 2018). In addition, the research group in China has also carried out extensive research on using similar DEM method in simulating ice–structure interactions (e.g., Feng et al. 2015; Ji et al. 2013).

Cohesive Element Method

This method is available in most existing commercial software programs. It focuses more on the fracture modeling. The rubble transportation part is more an existing “default” feature that most FEM software have.

The cohesive element method is to characterize the material failure process following the so-called cohesive zone theory using “cohesive element.” Comparing to the conventional finite element, whose constitutive relationship is stress (unit: [Pa]) and strain (unit: [1]) based, the cohesive element is characterized by traction (unit: [N]) and separation (unit: [m]). The framework of this method has been described by Konuk et al. (2009a, b). It has been widely utilized in ice

Numerical Simulation Floe Ice–Sloping Structure Interactions, Fig. 3 Analytical ice fracture hybrid with DEM ice rubble transport simulation (simulated by SAMS (ArcIso 2020))

engineering since (e.g., Gürtner et al. 2008a, b, 2009; Konuk and Yu 2010; Feng et al. 2016; Kuutti et al. 2013; Wang et al. 2018, 2019; Lu et al. 2012, 2014).

Figures 4, 5, 6, and 7 show an example of such simulation concerning ice fracturing and ice

rubble’s transportation around the structure using inserted cohesive elements.

eXtended Finite Element Method (XFEM)

The XFEM can only simulate the fracturing process of ice, but not the fragmentation process. It is

Numerical Simulation Floe Ice–Sloping Structure Interactions, Fig. 4 A sloping structure enters an ice sheet

Numerical Simulation Floe Ice–Sloping Structure Interactions, Fig. 5 Ice fracture happens within the ice sheet

Numerical Simulation Floe Ice–Sloping Structure Interactions, Fig. 6 Bottom view showing the generated ice fragments

Numerical Simulation Floe Ice–Sloping Structure Interactions, Fig. 7 A transparent view showing the not-yet-failed cohesive elements (in blue color) and rubble transport around the structure

a mesh independent method, which means the crack can propagate across the predefined mesh thanks to the Heaviside function to describe the

displacement field jump over the crack (Belytschko and Black 1999). It is useful to simulate large cracks within sea ice; but not the

Numerical Simulation Floe Ice–Sloping Structure Interactions, Fig. 8 Illustration of using XFEM simulating the splitting crack within an ice floe

fragmentation process. The fragmentation process should be simulated by a different numerical method, for example, DEM.

Figure 8 illustrates an example of using XFEM to simulate the splitting crack within an ice floe arbitrary geometry (Lu et al. 2018a). Fig. 8a shows the simulated crack path within the ice floe, which corresponds well with the actual interaction image (i.e., rectified image from an onboard camera system (Lu et al. 2016b)).

Lattice Model

Lattice model is a discrete approach and can be utilized simulate both the fracture and upcoming fragmentation of sea ice. Mass points (or bodies) are connected by lattice, either being spring, truss, or beam elements are utilized to formulate the ice body. If only the spring and dashpot type connector is used, the lattice model is rather similar to the conventional DEM method's formulation.

This method has been utilized to simulate the crushing failure of sea ice against vertical structures (Dorival et al. 2008; Jirásek and Bazant 1995); to the modeling level ice and ice ridges (Berg 2015); and has been evaluated by van Vliet (2018) for various ice failure modes and ice–structure interactions.

Peridynamics

The peridynamic method is also a discrete approach that gains popularity within ice engineering in recent years. Its formulation, implementation, and application in ice engineering can be found in related literatures (e.g., Oterkus et al. 2017; Vazic et al. 2019, 2020).

Applications

Numerical simulations of ice–structure interactions have seen increasing applications in recent years, partly due to the increase in our computational capacity and partly due to our ever-growing knowledge in simulating ice actions. The pertinent applications of each of the presented method can be found in the attached references. Here, we will stress one of the main advantages/applications of introducing numerical simulations in the concurrent Arctic offshore design loop. The current practice in designing an Arctic offshore structure, being an offshore platform or an icebreaker, involves model ice tank tests (Evers and Jochmann 1993; Timco 1984). However, model ice tank tests, despite its advantages of offering us well-controlled environmental conditions, suffer from: (1) slow preparation time; (2) limited variations in structural manufacturing due to resource limit; and (3) limited boundary conditions, comparing to numerical simulations. Additionally, as the ice conditions get more complicated, for example, the floe ice conditions, the ice tank tests' repeatability becomes questionable (van den Berg et al. 2020). Thus, introducing the above presented numerical simulation methods into the existing design loop is of great significance in the sense that it contributes to an essential complimentary component to the existing methods. This combination of “numerical ice tank” + “physical ice tank” can largely extend and optimize test scenarios, therefore leading to more efficient, more reliable, and less expensive Arctic structural designs.

Introduction

Good estimate of ice force is necessary to design ice-going ships because good hull shape design improves icebreaking and maneuverability and reduces the ice force acting on the hull, which reduce the required power. Currently, numerical models of ship–ice interactions have been developed and used for various ship and ice conditions. Four typical ice conditions must be considered when developing appropriate numerical models for ice-going vessel: level ice, pack ice, ridge ice, and icebergs. A main factor to assess ice-going ships is their performance in level ice. Early numerical modeling of level ice was conducted to calculate the icebreaking of continuous plate ice and to estimate the ice force (Valanto 1992, 2001). The drifting and impact of distinct ice floes should be considered for ship–ice interactions in pack ice (e.g., Hansen and Løset 1999; Wang and Derradji-Aouat 2010). Ship penetration in piles of rubble is a greatly challenging issue for the modeling of ships passing through an ice ridge (Gong et al. 2019). For ridge fields, estimations based on theoretical and empirical formulae are all that are available at present (e.g., Kuuliala et al. 2017; Myland 2014). The impact mechanism of ship–iceberg collision and material modeling of icebergs are difficult to construct in numerical models in ship–iceberg interaction (Liu and Amdahl 2010; Liu et al. 2011).

Normally, simulations calculate the global ice force (ice resistance) acting on the ship hull. Numerical results are used to estimate ship performance in the early design stage, such as the h – v curve and the required thrust (e.g., Su et al. 2010). The h – v curve represents the relation between ship speed and thickness under different ice conditions, which demonstrates icebreaking capability. Recently, numerical models are applied to more complicated sea ice conditions, such as dynamic positioning (DP) in ice (e.g., Metrikin 2014; Nguyen et al. 2009) and ice management in a marginal ice zone (MIZ) (e.g., Hamilton et al. 2011; Scibilia et al. 2014). Liu et al. (2008) and Lubbad and Løset (2011) developed real-time simulations for ship–ice interactions. These numerical models, if calibrated and validated properly, are useful tools not only for the early

design stage but also for crew training, for efficient operation in ice, and for onboard support systems in arctic operations.

This entry presents specific examinations of the numerical modeling used for most common ship–ice interactions: ship and level ice interaction. In terms of ship and level ice interaction, the failure of a flexural ice sheet and the motion of broken ice floes are considered. Numerical models for other ship–ice interactions can be developed using models both of the continuous plate ice and discrete broken ice.

Review of Numerical Models for Ships in Continuous Ice

Ship–ice interaction in the level ice is a repetitive phenomenon of ship–ice collisions and icebreaking of ice sheets. The first attempt to simulate the repetitive contacts and icebreaking is the numerical modeling of ice and conical structure interactions proposed by Izumiyama et al. (1992). In the numerical modeling, the icebreaking (crack) pattern and size are obtained using experimental data of the model tests in the ice basin. The icebreaking force is calculated using the ice failure model based on the plastic limit theory proposed by Ralston (1977). They mentioned that it is possible, in principle, to apply a similar method to prediction of ice resistance of ship.

Wang (2001) proposed numerical modeling for ice–cone interaction using a similar approach to that reported by Izumiyama et al. (1992). A hierarchy of discrete events that include crushing, bending, and rubble formation is adapted to simulate continuous ice–cone contact events. The ice–cone contact point is calculated using the grid method (GM), which represents the ice sheet as a regular grids. Contact occurs when the ice edge line is on the waterline of the structure. After the ice bending failure, a new ice edge appears by removal of the grids within the broken ice floe from the main ice sheet. The icebreaking force and the broken ice geometry are derived respectively from the empirical formulae proposed by Kashtelian (Kerr 1975) and results reported by Varsta (1983). This model calculates only repetitive peak force by the ice failure. It

neglects the rotation and sliding up of the broken ice floes. The developed model calculated the time history of ice force acting on the jacket structure.

Valanto (1992) developed a two-dimensional (2D) numerical model of icebreaking at the waterline of a ship advancing in level ice. The model specifically examines the ice sheet breaking cycle, incorporating the floating ice–fluid dynamics, ice edge crushing, floating ice failure, and broken ice rotation. The dynamic ice–fluid response and ice bending are assessed quantitatively using the assumption of potential flow with complicated boundary conditions on the ice sheet–fluid interface. The ice crushing and rotation of broken ice sheets were analyzed using geometrical formulations of ship–ice interaction. The 2D numerical model included effects of the compressive membrane stress in the ice sheet, which postpones the ice sheet failure (Valanto 1997). The numerical modeling has been extended to a three-dimensional (3D) problem, in which the underwater components of ice resistance were evaluated using the semiempirical formula presented by Lindqvist (1989) (Valanto 2001).

Many other researchers have adopted and modified the continuous contact between the structure and level ice derived by Wang (2001). Sawamura et al. (2009) proposed a numerical modeling of a ship advancing into level ice. The numerical model specifically examines icebreaking at the waterline and neglects broken ice rotating and sliding against the underwater hull. The repetitive ship–ice contact and plate ice failure are calculated using physically based modeling, which is often used in computer graphics, and plate bending obtained using finite element (FE) method. Nguyen et al. (2009) applied Wang's model to a DP system of ships in level ice. Su et al. (2010) developed a 2D numerical model using an empirical formula of icebreaking, crushing, and ice submergence. Ship motions are described by three degrees of freedom (3DOF) rigid motion equations in which the motions include surge, sway, and yaw. The ship–ice contact is calculated using more refined contact procedures based on GM method (Wang 2001). Numerical results (h – v curve and turning diameter) showed agreement with measured data obtained from a real trial of a ship turning in level ice. Su et al. (2011)

applied numerical methods to simulate a ship advancing into uniform and randomly varying ice conditions. This numerical model was extended to a 6DOF (surge, sway, heave, yaw, roll, and pitch) ship–ice interaction (Tan et al. 2013). The numerical models using a similar approach to that described by Su et al. (2010) were presented and used in different ship–ice interactions in level ice (e.g., Li et al. 2019; Zhou et al. 2016, 2017).

Lau et al. (2004) proposed real-time simulation of a ship maneuvering in level ice. The model realizes a short calculation time because analytical modeling of the icebreaking and buoyancy component is adopted. Liu et al. (2008) developed a software package of ship and level ice interaction using the numerical modeling of Lau et al. (2004). Lubbad and Løset (2011) developed real-time simulation of 3D ship–ice interactions. They combined the physics engine (3D rigid body simulation) with a self-developed icebreaking program based on a theoretical approach. In the simulation, the ice floes are represented as three-dimensional bodies with 6DOF. The ship motions and those of all ice floes (ship–ice and ice–ice interactions) are solved. The simulation was updated and validated using full-scale tests (Lubbad et al. 2018). Kubat et al. (2010) and Sayed and Kubat (2011) proposed a numerical simulation of ship transit through ice cover and simulated the pressure ice interaction. In the model, the governing equations account for the conservation of mass and the momentum of the ice cover. The ice cover is regarded as breaking in a rigid-plastic fashion. Many numerical models of ship and level ice interaction have been presented using a different approach (e.g., Aksnes 2010; Liu et al. 2018; Zhang et al. 2019). For the application of numerical simulation to the design for ice-going vessels, further improvement of ship–ice interaction is needed (Li et al. 2018).

Mechanism of Ship and Level Ice Interaction

Ship–level ice interaction is a repetitive process with breaking, rotating, sliding, and clearing. A ship collides with level ice at the waterline

when it advances into the level ice. After a ship collides with a plate ice, ice edge crushing and plate ice deflection occur. When the ship advances further, the crushing area at the ice edge and the vertical deflection of the plate ice increase. At the same time, the stress in the plate ice induced by the plate ice deflection increases. When the stress in the plate ice exceeds the ice strength limit, ice failure occurs in different failure modes depending on the loading conditions e.g., bending, buckling, and splitting. After ice sheet failure, the broken ice floe is accelerated further and rotated by the ship hull until the ice floe is parallel to the hull. Subsequently, the broken ice floes slide along the underwater hull. Figure 1 portrays the icebreaking process.

The maximum ice force during the above ship and level ice interaction is induced by the ice failure. Therefore, icebreaking at the design waterline is the most relevant to evaluate the icebreaking performance. However, the ice force of the rotating and sliding of broken ice floes (ice submergence force) is smaller than the peak force

of the ice failure. The broken ice submergence engenders collision and friction force along the underwater hull, which makes a great contribution to the total ice resistance during the icebreaking cycle. Figure 2 presents idealization of the time history of ice force.

Many researchers divide ship-level ice interaction into icebreaking at the waterline and ice submergence underwater by the hull in their numerical model. Icebreaking is a simple physical phenomenon that can be represented by a quasi-2D model because the numerical simulation of 2D model is simulated with less computational time than those of the 3D model. Regarding ice submergence, interaction between the underwater hull and the broken ice floes is a complicated phenomenon. The ice submergence force is therefore often estimated using an empirical formula. The 3D numerical simulation of ship and level ice interaction including level icebreaking and ice submergence requires a powerful computer. The fluid force induced by ship-ice interactions is another difficulty hindering numerical modeling.

edge crushing and deformation of the plate ice, (c) plate ice failure, and (d) rotating and sliding of broken ice floes

Numerical Simulation of Ice-Going Ships,

Fig. 2 Idealized time history of ice force

Ship–Ice Contact

When a ship advances into level ice, the ship collides with the ice edge at several locations at the ship waterline. The ice edges at the contact points are broken by crushing. The contact force at the ice edge increases concomitantly with increasing crushing area. For the numerical modeling, the precise contact points and the crushing (contact) area must be calculated. The 3D modeling requires a complicated algorithm and computational power. A 2D model at the waterline is therefore adopted in many numerical model (e.g., Lubbad and Løset 2011; Nguyen et al. 2009; Su et al. 2011). An example of modeling of the ship–ice contact point and the crushing area in the simulation is shown below (Fig. 3).

Numerical Simulation of Ice-Going Ships, Fig. 3 Contact detection and intersection area (crushing area)

1. The ship waterline and ice edge are discretized as closed polygons.
2. Nodes and polygons that enter the polygon of both the ship and ice are identified.
3. The intersection area (crushing area) is defined at each time step.
4. Contact force is calculated based on the intersection area and the ice wedge angle.

The algorithm should be improved to maintain accuracy of the contact point and crushing area with less computation time. Zhou et al. (2016) adopted the point-in-polygon method. This algorithm specifically addresses on only the ice edges where ship–ice interaction might occur. Sawamura et al. (2009) adopted the circle contact detection algorithm to detect the ship–ice contact

points. The algorithm is often used in real-time animation of computer graphics. In his developed software package, Metrikin (2014) presented computational techniques of the ship and ice field modeling (mesh generation of the ice floes) and ship–ice interaction (collision detection and icebreaking).

Plate Ice Failure

In the ship–level ice interaction, the predominant failure mode is bending. First, the theory of an elastic plate resting on the elastic foundation, as a Winkler foundation (Fig. 4), was formulated to estimate plate ice bending behavior (e.g., Kerr 1975). Nevel (1961) calculated the deflection of the narrow infinite wedge, which considers radial and circumferential cracks when an ice sheet is

Numerical Simulation of Ice-Going Ships,
Fig. 4 Semi-finite plate resting on an elastic foundation
 with a radial and circumferential crack

broken by bending. Kashtelian (Kerr 1975) developed an expression for the bearing capacity of the wedge ice with edge force. These formulas deal with a floating plate with static load, but the actual state of the ship–ice interaction is dynamic load. However, static formulae are adopted by many numerical models because numerical implementation is simple (e.g., Lubbad and Løset 2011; Su et al. 2011).

Plate ice bending in ship–ice interaction is a rapid phenomenon. Therefore, dynamic effects of water underneath floating ice must be included in the bending behavior. Analytical formulations of the dynamic response attributable to an edge force on the simple shape ice sheet have been proposed (e.g., Fox 1993; Zhao and Dempsey 1996). These models are useful to estimate the bearing capacity by plate bending. However they cannot be used directly in the numerical modeling because the complicated wedge-shaped ice is generated by ship–ice interactions. Analytical solutions deal only with the simple ice shape. Sawamura et al. (2008) simulated bending behavior of wedge-shaped floating ice with a rapid edge force using fluid–structure interaction (FSI). They produced a database of the bending failure of the wedge-shaped ice and implemented this database into their numerical model (Sawamura et al. 2009). In addition to the vertical force (bending force), horizontal force (in-plane force) might also affect the ice failure mode. The in-plane stress by the horizontal force delays deflection of the sheet ice. Consequently, the icebreaking length and force

increase. Derradji-Aouat (2003) provided formulation for the 3D failure criterion of saline ice based on the multi-surface failure theory, which includes the effects of both vertical and horizontal force. Sawamura et al. (2010) investigated the effects of the horizontal force on the icebreaking during ship–level ice interactions using the FSI.

In ship–ice interactions, ice sheet failure patterns are characterized by radial cracking and circumferential cracking. According to the observations, radial cracks initiate from the ship–ice collision point. Subsequently, increasing force acting on the ice edge engenders circumferential cracks. Lubbad (2011) adopted both radial and circumferential crack failure criteria proposed by Nevel (1961) in his numerical simulation. Recently, fracture mechanics approaches have been applied by several researchers for crack initiation and crack propagation in floating ice sheets (e.g., Dempsey and Mu 2014; Lu et al. 2016). Nevertheless, ice failure based on observations from model-scale and real-scale experiments is adopted. For ice sheet crack pattern, a simple broken floe (e.g., circle ice floe) is assumed in most numerical models.

Ship in Broken Ice Floes

The ice force attributable to rotating and sliding of the broken ice floes is induced by buoyancy and ship–ice collision along the underwater hull. The ice submergence is a complicated phenomenon that entails many uncertainties. Actually, 3D simulation of the ice submergence requires many computational power. For this reason, most numerical models apply the empirical formulae to evaluate ice submergence force (e.g., Liu et al. 2008; Nguyen et al. 2009; Su et al. 2010).

To simulate ice submergence, an efficient 3D numerical model is required. Lubbad and Løset (2011) used NVIDIA PhysX, a real-time physics simulation engine including a rigid body dynamics, soft body dynamics, and particles and fluid simulation (NVIDIA Corp. 2018), to solve the equations of rigid body motions in 6DOF for all ice floes. They combined the self-developed icebreaking module with NVIDIA PhysX and simultaneously simulated both icebreaking and ice submergence. Konno and Mizuki (2006)

used the Open Dynamics Engine Library (Smith 2004), which is also an open-source physics library, to implement a physically based modeling of ship–ice floes interactions. They predicted ice-clearing resistance with the 3D numerical simulation of pre-sawn ice test. Konno (2009) applied the same physically based modeling to the ship in brush ice channel. Sawamura and Tachibana (2011) developed the numerical model to calculate the ice submergence force of the ship in pre-sawn ice using physically based modeling. The physics engine cannot support icebreaking: the physics engine is available for unbreakable ice floes.

Lau (2006) presented numerical modeling of ship maneuvering in level ice conditions using discrete-element method (DEM). The discrete elements in the ice channel are divided into the broken ice floes with the observed icebreaking pattern (pre-sawn ice). Each ice piece is connected by stiffness springs. The stiffness spring in most of the numerical model using DEM must be chosen using trial and error based on the experimental and measured data. DEM is an effective method to simulate the discretized bodies such as broken ice. Therefore, it has been adopted for numerical modeling of a ship in pack ice (e.g., Hansen and Løset 1999; Ji et al. 2013; Wang and Derradji-Aouat 2010; Zhan et al. 2010) and ridge ice (Gong et al. 2019). A reasonable sea ice model must be required in the DEM simulation because 3D simulation requires powerful computer resources and long computational times. The fluid modeling of ship–ice interactions is another challenging difficulty for numerical modeling. Ventilation phenomena are not considered in most numerical models.

Numerical Modeling of a Ship in Continuous Ice

Methodologies used for the simulation of the repetitive ship–ice collision and icebreaking at the waterline are introduced. In this section, the numerical modeling proposed by Su et al. (2010) is explained mainly, because their theories can be implemented easily into the numerical model and

many researchers have referred this modeling method (e.g., Nguyen et al. 2009; Sawamura et al. 2009; Zhou et al. 2016). The simulation evaluates repetitive ship–ice collision and icebreaking at the waterline. Ice submergence under the waterline is evaluated using the empirical formula.

Motion Equation

The ship motion is described by 3DOF rigid body equation in 2D model and 6DOF in 3D model as

$$(\mathbf{M} + \mathbf{A})\ddot{\mathbf{x}}(t) + \mathbf{B}\dot{\mathbf{x}}(t) + \mathbf{C}\mathbf{x}(t) = \mathbf{F}(t), \quad (1)$$

where $\mathbf{M}$, $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$, respectively, denote the mass, added mass, damping, and restoring force matrices. Also, $\mathbf{F}$ represents forces and the moment vector acting on the ship; $\mathbf{x}$ denotes the ship displacement vector. The force and moment vector can be decomposed into the following components:

$$\mathbf{F} = \mathbf{F}_H + \mathbf{F}_P + \mathbf{F}_R + \mathbf{F}_{Ice}. \quad (2)$$

Therein, subscripts H, P, R, and Ice, respectively, denote forces of hydrodynamics, propeller, rudder, and ice. For the motion equations for the ice-going vessels, the specific component is only the ice-induced force $\mathbf{F}_{Ice}$. Furthermore, ice force can be written as

$$\mathbf{F}_{Ice} = \mathbf{F}_{break} + \mathbf{F}_{sub} + \mathbf{F}_{others}, \quad (3)$$

where $\mathbf{F}_{break}$ signifies the icebreaking force, $\mathbf{F}_{sub}$ denotes the ice submergence force, and $\mathbf{F}_{others}$ stands for other force component induced by ship–ice interaction. At each time step, Eq. (1) is solvable by the numerical integration such as Newmark method and Runge–Kutta method.

Ice Contact Force

At the ship–ice contact, ice crushing occurs at the ice edge. The contact force increases proportionally with increasing crushing area. When the ice pressure on the contact surface is assumed to be constant, the contact force at the contact surface between the ship hull and ice edge is given as

$$F_n = f_{ic} A_c \sigma_c, \quad (4)$$

where F_n stands for the contact force normal to the crushing area, f_{ic} expresses the contact coefficient, A_c denotes the crushing area, and σ_c signifies the compressive strength of ice. Contact coefficient f_{ic} accounts for irregularity of the contact area. Valanto (2001) used the value of 0.5 for the contact coefficient for the ship hull–full-scale level ice contact in his numerical model. Crushing area A_c increases with the ship penetration distance into an ice edge. The plate ice deflection is very slight compared to the characteristic length of ice. It is assumed to be zero before ice bending failure in the numerical modeling because of simplicity of the calculation. Crushing area A_c is calculated numerically or geometrically using the relation between the ship hull and ice edge, as described in section “Ship–Ice Contact.”

The kinematic friction force is presented on the crushing surface. Coulomb type friction is assumed, which direction of frictional force is opposite to the relative velocity. The total ice force attributable to ship–ice interaction is calculated as the sum of the contact force and the friction force. The total ice force is divided into vertical and horizontal components at the contact surface, as presented in Fig. 5. It is derived as the following equations.

$$\begin{aligned} F_Z &= f_{ic} A_c \sigma_c (\cos \varphi - \mu \sin \varphi) \\ F_H &= f_{ic} A_c \sigma_c (\sin \varphi - \mu \cos \varphi). \end{aligned} \quad (5)$$

Therein, F_Z and F_H , respectively, denote vertical and horizontal components of the ice force, φ

signifies the slope angle, and μ stands for friction coefficient between the hull and contact surface. The ice edge is subjected to a sudden downward force F_Z , which deflects the ice sheet by plate bending. The horizontal component F_H might affect the floating ice bending. However, it is often neglected in the ice failure calculation. Ice crushing takes place at the ice edge until the crushing area increases the downward force sufficiently to initiate the flexural failure. Otherwise, only the ice edge is crushed without bending failure.

Ice Failure and Breaking Force (F_{brek})

The floating ice is deflected by the downward force. It is eventually broken by bending failure. The ice failure criterion with the bearing force of floating ice is used. Ice bending failure occurs when downward force F_Z exceeds the bearing force of the floating ice. The bearing force of the floating ice with a quasi-static edge force is calculated according to Kashtelian (Kerr 1975).

$$P_f = C_f \left(\frac{\theta}{\pi} \right)^2 \sigma_f h_i^2 \quad (6)$$

Therein, P_f stands for the failure force of the floating ice, θ represents the ice wedge angle, σ_f denotes the flexural strength of ice, h_i expresses the ice thickness, and C_f is an empirical coefficient. Kashtelian suggested a small value (approx. 1.0) for C_f , whereas Su et al. (2010) adopted a value of 3.1 by comparison of ice resistance with the empirical formula reported by Lindqvist (1989).

Numerical Simulation of Ice-Going Ships,
Fig. 5 Ice force between the ship and ice edge

After bending failure, a circular ice cusp is broken off the plate ice. The broken cusp length is determined using the formula presented in Wang (2001), which is based on methods described by Enkvist (1972) and Varsta (1983).

$$r_f = C_l l (1 + C_v v_n^{\text{ref}}) \quad (7)$$

Therein, r_f denotes the circumference crack length, v_n^{ref} stands for the velocity component normal to the contact surface, C_l and C_v express empirical formulae, where C_l has positive value and C_v has negative value, and l represents characteristic length of ice given as

$$l = \left(\frac{E h_i^3}{12(1 - \nu^2) \rho_w g} \right)^{\frac{1}{4}} \quad (8)$$

where E represents Young's modulus, ν stands for Poisson's ratio, g signifies the gravitational constant, and ρ_w denotes the density of seawater.

Ice Submergence Force (F_{sub})

The ice resistance attributable to ice submergence is estimated using empirical formulae. Su et al. (2010) adopted the submersion resistance formula proposed by Lindqvist (1989).

$$\begin{aligned} R_{\text{sub}} &= R_s \left(1 + 9.4\nu / \sqrt{gL} \right) \\ R_s &= \Delta_p g h_i B \left\{ \frac{T(B+T)}{B+2T} + \mu (A_b + \cos \phi \cos \psi A_f) \right\} \\ \psi &= \arctan (\tan \phi / \sin \alpha) \end{aligned} \quad (9)$$

Therein, R_{sub} and R_s , respectively, denote the ice submergence resistance with and without speed dependence, ν denotes the ship speed, L , B , and T , respectively, represents the ship length, breadth, and draft, Δ_p is the density difference between the water and the ice, α , ϕ , and ψ respectively, denotes the waterline entrance angle, stem angle, and angle between the normal of the hull and a vertical vector, and A_b and A_f , respectively, represent the area of flat bottom and the bow of the ship. Zhou et al. (2016) used the model proposed by Spencer and Jones (2001) in which

submergence resistance is divided into buoyancy and ice-clearing components. Lubbad and Løset (2011) numerically evaluated the ice submergence force using the 3D rigid body simulation of the physics engine.

Simulation of Ship–Ice Interaction

The numerical model mainly divides the ship–ice interaction into four components: ship motion, ship–ice contact, icebreaking along the waterline, and ice submergence under the waterline.

1. Ship motion is calculated using rigid body motion equations using the icebreaking and submergence force at the previous time step (motion equation).
2. Ship–ice contact along the waterline is calculated using contact detection technique. Subsequently, the ship–ice contact conditions (ice crushing, ice contact force) are updated (ice contact force).
3. Ice failure is judged using the ice failure criterion. If bending failure occurs, then the ice cusp is broken off the plate ice (ice failure and breaking force).
4. Ice submergence force and the positions of all broken ice floes (if necessary) are calculated (ice submergence).

The processes presented above are calculated separately and are summed to complete one numerical cycle in each time step.

Figure 6 presents the computed ice channel, breaking pattern, and time history of icebreaking force calculated using the 2D numerical model based on an earlier report of the literature (Sawamura et al. 2017). The principal dimensions of the ship are 136 m length, 29 m width, 10 m draft, and 20° bow angle. The ice sheet is 2 m thick. Young's modulus of the plate ice is 254 MPa. The ice flexural strength is 575 kPa. The compressive strength of the ice is 820 kPa. The friction coefficient between the ship and ice is 0.075. The icebreaker advances with constant speed of 1 m/s. The ship motion equation is neglected. The total ice force is obtained as the sum of the ice submergence force to the icebreaking force as depicted in Fig. 6.

Numerical Simulation of Ice-Going Ships, Fig. 6 Numerical results of ice channel, breaking pattern, and time history of icebreaking force

Numerical Simulation of Ice-Going Ships, Fig. 7 Relation between ice resistance and ship speed and comparison with the model test data and ice resistance formula

In Fig. 7, the numerical results are compared with the ice resistance of model test data and Lindqvist (1989). The numerical resistance shows good correlation with the model test and the empirical formula. The erratic point is shown, however. This irregularity of the ice resistance is apparent also in the numerical results reported by Su et al. (2010) and by Liu et al. (2008). These results demonstrate that the numerical results are sensitive to the ship and ice conditions.

Future Directions

Numerical simulation can evaluate the icebreaking process of a ship in simple ice conditions (level ice and uniform pack ice field). Further improvement of ship–ice interaction is necessary when the numerical simulation is applied to the design for ice-going ships. Recently, numerical models apply more complicated ship–ice interactions (DP and ice

management operation in MIZ). The numerical model of a ship in an MIZ should incorporate consideration of ice–wave interactions because the ship is affected by small ice floes and waves in the MIZ. The ship in a ridge field and ship ramming operations remain as challenging topics for numerical modeling. Verification of the numerical model must be done through comparison with real ship trials. However, many difficulties might arise with collection of data in the actual ice and ship conditions. The model- and real-scaled measurement technique should also be improved to acquire and accumulate verification data. The fluid model during ship–ice interactions and the failure criteria of bending, crushing, and other failure modes of floating ice plates should be investigated to improve the numerical model accuracy.

Physical tank

Definition

Numerical tank is a set of highly efficient computing software which is programmed systematically by using advanced hydrodynamic model and numerical algorithm as well as professional experience. Combined with advanced computer and Internet service, Numerical Tank can perform highly accurate virtual tests on hydrodynamic performance for marine structures and hence meets the requirements for research, design, and application in the field of naval architecture and ocean engineering ([Numerical tank](#)).

The research and development of the Numerical Tank Application System is supposed to have high virtual test accuracy standards and rely on

high efficient hydrodynamic model; it also needs the verification support of physical tests data. In addition, the Numerical Tank Virtual Test System, in its process of development, made integrated packaging of experts' experience in geometrical modeling, mesh discretization, and computing parameters so to acquire stable and reliable virtual test results (Zhao et al. [2014](#)).

Compared with the physical tank in terms of test objects, test environment, and test content, the numerical tank not only “tests” the overall hydrodynamic force and motion response but also “tests” the fluid information such as fluid velocity and pressure with good accuracy more easily. The test results satisfy various requirements of ship hydrodynamic performance evaluation and optimization. In the present trend of development, it is expected that the numerical tank will go beyond physical tank and be able to perform the full-scale simulation of the motions and loads for the marine structures, which will contribute to the design of more optimal ships and offshore platforms and serve the base of intelligent marine operation. The numerical tank technology brings the revolutionary change to the design methods of marine engineering equipment, so it carries great significance in engineering.

Scientific Fundamentals

The ship hydrodynamic performance measurement is mainly carried out through physical tank test for a long time. There are various types of physical tanks around the world, which include towing tank, ship seakeeping tank, ship maneuvering tank, cavitation water tunnel, etc. These physical tanks can perform various tests on ship hydrodynamic performance including ship forward speed, ship motions in waves, ship maneuverability, etc. It can also provide guidance in the selection of optimal ship. Currently, the ship hydrodynamic performance test in the physical tanks is still the most important and reliable way to test the ship's hydrodynamic performance.

However, the traditional physical tank test has the following disadvantages:

- (a) It usually requires high costs of installation and long operating time.

- (b) New unforeseeable requirements for the test are sometimes difficult to be satisfied by the physical tanks.
- (c) It is impossible to simulate the hydrodynamic loads for full-scale ships in the physical tank due to the limited physical tank dimensions.
- (d) The interruption of the space and time in the ship design cycle, during the physical test, remains the dominant bottleneck for the intelligent design.

Faced with the requirements from the new regulations regarding the low emission and safety on the ship design, and the challenges of the harsh weather conditions on the design of offshore equipment in deep water, the traditional physical tank cannot adapt to the development of the modern technologies, which has the limiting characteristics of big investment, long operating time, and limited dimensions. With the fast development in computer hardware technology, as well as the continued improvement in computational fluid dynamics (CFD) technology and the software functions, CFD technology has found its wide application in optimizing of hydrodynamic performance for marine structures. In order to adapt to the change from the physical tank test to the virtual test in the research and development for the marine structures, the idea of the numerical tank technology is hereby proposed, which combines the CFD technology and its application experiences during the hydrodynamic performance simulation.

The core basis of the numerical tank is the CFD technology, which mainly includes the potential flow and viscous flow numerical models. The practical effectiveness of the numerical tank lies in the obtained simulation experience based on the fluid characteristics of the ships and other marine structures. In addition, the high efficiency application of the numerical tank also involves the parallel computing techniques, visual technology, Internet technology, etc.

Key Applications

The numerical tank can perform the ship resistance and propulsion virtual test, propeller cavitation-induced exciting force virtual test,

ship seakeeping virtual test, ship maneuvering virtual test, ocean wave environment virtual test, motion and loads virtual test for offshore platform, and VIV (vortex-induced vibration) and VIM (vortex-induced motion) virtual test. It is expected that the numerical tank will be able to perform full-scale ship virtual test in real sea environment and full-scale offshore platform motion and loads virtual test in real sea environment. The numerical tank not only supports the digitization and intelligent design for the marine equipment but also forms an important foundation for intelligent ocean exploration and navigation.

Based on our research in China Numerical Tank, some applications are presented about the numerical tank virtual test for ships and offshore structures.

Wave Added Resistance Virtual Test Numerical Tank

In order to serve in the estimation of EEDI whether factor or minimum propulsion power ([Guidelines on the method of calculation of the attained energy efficiency design index \(EEDI\)](#)), the wave added ship resistance virtual test is developed in China Numerical Tank (CNT). The virtual test is developed based on three-dimensional potential flow theory with forward speed in time domain and is solved using innovative Taylor Expansion Boundary Element Method (Duan et al. 2020; Duan et al. 2015a, b), which is therefore named as CNT-TEBEM WAR. The virtual test is integrated with intelligent parameters setting including the panel mesh generalization in free surface and control volume boundary. Its main functions are as follows:

- The wave-induced ship motions and wave added ship resistance in regular/irregular waves.
- The virtual test is suitable for primary large commercial ship types such as container ships, bulk carriers, and oil tankers.

The wave added ship resistance virtual test numerical tank can be operated in popular PC with Windows operating system or High-Performance Computing Cluster. The computational efficiency is quite high, and it takes about only 5 min to finish the wave added resistance computation under one

incident regular wave using popular PC, which is much faster than the viscous flow model with the same accuracy.

In the following, the wave added resistance virtual test is validated with model test and another commercial software viscous flow ISIS-CFD software (Queutey and Visonneau 2007; Theoretical Manual 2011). The model test is performed at Shanghai Ship and Shipping Research Institute (SSSRI) (Figs. 1, 2, 3, 4, 5).

Ship Motions Virtual Test Numerical Tank

In the traditional ship seakeeping physical model test, the wave-induced ship motions are often tested. In the China Numerical Tank, the wave-induced ship motions virtual test is developed. The virtual test is based on the three-dimensional time domain potential flow theory using impulse response function formulation. The matched boundary integral equations are used to solve the fluid potential, and the virtual test is developed by the Taylor Expansion

Numerical Tank, Fig. 1 The physical model test of wave added resistance for a 14000TEU container ship performed at SSSRI

Numerical Tank, Fig. 2 The hull panel for a 14000TEU containership

Numerical Tank,

Fig. 5 The pitch motion RAO from China Numerical Tank compared with viscous flow commercial software and physical model test at regular head wave ($F_n = 0.158$)

Boundary Element Method, which is therefore named as CNT-TEBEM WIM. Its main functions are as follows:

- Wave-induced ship motions virtual test at various wave headings in regular waves
- Wave-induced ship motions virtual test at various wave headings in irregular waves
- The probability test of green water, slamming, and propeller emergence virtual test in irregular waves

The computational efficiency is quite high, and it takes only about 30 min to finish one RAO

curve for one wave heading and forward speed using popular PC. In the following, the accuracy of the wave-induced ship motions virtual test is verified with the model test for YUPENG ship, where the model test is held at China Ship Science Research Center (CSSRC). The model test is performed for a self-propulsion ship model at various wave headings (Figs. 6, 7, 8, 9).

Ship Roll Damping Virtual Test

In the traditional ship seakeeping model test, the calm water roll damping test is often tested in order to capture the viscous ship roll damping coefficients in the ship roll motions predictions

Numerical Tank, Fig. 10 Validation of free decay rolling for DTC container ship

using potential flow theory. In the China Numerical Tank, the ship roll damping free decay virtual test is developed.

The virtual test is developed by unstructured body-fitted mesh viscous flow model, applicable for the vortex simulation of ship rolling. The parallel computing algorithm based on MPI is used; the parallel computing can be achieved at high-performance clusters. The automatic generation of the fluid mesh and integration of the intelligent setting for the computational parameters are performed in the development of the virtual test. Its main function is as follows:

- Ship roll damping virtual test by free decay

The virtual test accuracy is validated with the model test results. In the following, the free decay roll virtual test is performed for a Duisburg Test Case (DTC) container ship, and the test results are verified with the physical model test from Hamburg Ship Model Basin (HSVA) (Moctar et al. 2012) (Fig. 10).

Ship Green Water Slamming Virtual Test

In severe sea states, the large-amplitude wave-induced ship motions and slamming are of great

concern for the ship safety. In the China Numerical Tank, the ship green water slamming virtual test is developed and can be used to test the nonlinear ship motions and hydrodynamic slamming loads in bad weather.

The virtual test is developed using large-eddy simulation model and Cartesian grid algorithm (CNT-CGCFD) (Liao et al. 2018). The immersed boundary method is used to model the dynamic boundary on the ship surface. The parallel computing algorithm based on MPI is used; the parallel computing using 100 million grids can be achieved in supercomputing platform. The violent flow and slamming pressure during green water can be well captured.

Its main functions are as follows,

- Large-amplitude ship motions virtual test in regular/irregular waves
- Ship green water slamming virtual test

The virtual test accuracy is validated with the model test results. In the following, the green water virtual test for a 14000 TEU container ship is performed, and the virtual test results are compared with the model test. The model test is performed at Shanghai Ship and Shipping Research Institute (SSSRI) (Figs. 11, 12).

Wave-Induced Offshore Platform Motions Virtual Test

In order to obtain the wave-induced motions and operational limit in different sea states for offshore

Numerical Tank,

Numerical Tank,

Fig. 13 Validation of wave-induced motion virtual test for a semisubmersible at head regular waves

Numerical Tank,

Fig. 14 Validation of low-frequency moored surge motion virtual test for a semisubmersible at head seas ($H_s = 7.5$ m, $T_p = 11.7$ s)

platforms, the physical model test for the platform in waves is needed to be performed. In the China Numerical Tank, the offshore platform motions virtual test is developed and can be used to test the wave-induced motions for the semisubmersible platform in waves.

The virtual test is developed using three-dimensional potential flow theory. The solver is developed by the Taylor Expansion Boundary Element Method (Chen et al. 2018). Once the hydrodynamic loads have been calculated using three-dimensional potential flow theory, the dynamic coupled analysis for the platform/

moorings/risers can be performed in wind, wave, and current (Ma et al. 2015). In order to consider the viscous load contribution, semiempirical Morison's formula is used in the estimation of the hydrodynamic loads from the slender structural members in the platform. The virtual test is named as CNT-TEBEM FCA.

Its main functions are as follows:

- First-order wave-induced motions RAO test
- Low-frequency horizontal motions and mooring line tensions for the moored platform in combined wind, wave, and current

The virtual test accuracy is validated with the model test results. In the following, the physical model test for the wave-induced motions RAO and the low-frequency moored surge motion from a semisubmersible is performed at Harbin Engineering University (HEU) (Fig. 13) and China Ship Science Research Center (CSSRC) (Fig. 14).

Definition

Obstacle avoidance technology is a control strategy or method that the underwater vehicle system must have. It enables the underwater vehicle to search and confirm static or dynamic obstacles on its forward path and can actively take avoidance

measures to avoid collisions with obstacles and finally restore to the set path to continue to perform the specified task.

Scientific Fundamentals

With the advancement of technology, underwater vehicles have gradually become one of the most important tools for understanding and developing the ocean, which has greatly promoted the development of marine economy and related technologies; underwater vehicles are widely used in seabed topography in complex environments. At the same time, they provide effective technical support and guarantees for research in the fields of underwater ecology, underwater archaeology, and underwater geoscience. In order to enable the underwater vehicle to adapt to the complex and changeable marine environment and complete underwater detection tasks quickly, efficiently, and autonomously, it is required that the underwater vehicle must have dynamic route planning and autonomous obstacle avoidance functions. In the specified operating area, the underwater vehicles can seek a continuous path through all reachable points from the starting point of the operation to the target end, on the premise of effectively avoiding unknown obstacles.

General Underwater Vehicle

The main missions of the underwater vehicles are geological and biological surveys of the seabed

and water column, including benthic and pelagic missions which could last up to a specified period of time. The need for an automated piloting system, or at least an aided piloting system, is clear. The cruising speed for long working underwater vehicles is around 1 km, and their movements are measured by several onboard sensors feeding the obstacle avoidance system with the position, speed, and orientation of the vehicle in world coordinates. The positioning system will consist of a long-baseline system (LBL), a super-short-baseline system (SSBL), and of various inertial navigation sensors (INS), depending on the vehicle such as compasses, gyro-meters, and Doppler velocity log (DVL). Despite the different depths at which underwater vehicles work, the baselines systems are likely to be imprecise, and INS sensors will drift with time; the obstacle avoidance module does not require long-term accuracy as it is creating a local map of the environment. The drift of the INS sensors should be negligible on short periods and ensure the successful creation of a precise local map. Due to the particularity of the underwater environment, sonars have become the most practical detection equipment used by underwater vehicles.

Obstacle Detection Method

When addressing the problem of obstacle avoidance and path planning, the main problem encountered is the extraction of information from the sonar images to create a representation of the environment and can be interpreted in terms that are suitable for computation.

In the underwater vehicle case, the first aim is to detect and avoid obstacles. Therefore, the segmentation of the scene is the first and crucial task. It is also useful to know how these obstacles are moving with respect to the vehicle in order to take movement into account in the obstacle avoidance/path planning process. Once the obstacles' static and dynamic characteristics have been computed from the input data flow, a workspace of obstacles surrounding the vehicle is created. This workspace uses constructive solid geometry (CSG) to create a convex representation of the obstacles, which eases convergence of the path planning algorithm. The map of obstacles

surrounding the vehicle takes into account the obstacles currently in the field of view of the vehicle but also obstacles that have gone out of the field of view, which have been tracked in the near past, and whose position is still critical to the definition of a safe path for the vehicle (Petillot et al. 2001).

The obstacle avoidance system for underwater vehicles that can be designed (see Fig. 1) is modular in nature. Modularity is seen as a way to handle different needs within the same framework.

Segmentation Module

The purpose of this module is to identify the interesting regions of the image-containing obstacles. Considering the very nature of multibeam sonar images, the certainty grid approach is discarded, and the object-oriented description of the workspace is focused on. As the vehicle is moving close to the seabed, high backscatter seabed returns are expected. This backscatter must be estimated and removed when possible in the segmentation process.

Feature Extraction Module

After segmenting the image, potential obstacles and their characteristics (location, size, and area) will be calculated. These features are used to determine whether there is an obstacle in front of the underwater vehicle, and to identify whether the obstacle has been detected before. These functions will later be used to discard false alarms and track obstacles and other vehicles.

Tracking Module

Obstacles can be divided into two types, namely static obstacles and dynamic obstacles. This division method is mainly to facilitate the use of different obstacle avoidance strategies later. The tracking module will provide dynamic characteristics and models of obstacles according to the requirements of the obstacle avoidance system.

Workspace Representation

From obstacles and features extracted from the current image, a symbolic representation of the

Obstacle Avoidance Technology for Underwater Vehicle,

Fig. 1 Architecture of sonar-based, real-time obstacle avoidance and path planning. (Petillot et al. 2001)

vehicle’s surroundings is built outright. Combining this representation with previous instances of the vehicle’s environment, a dynamic workspace is built and constantly updated. It forms the basis for the path planning algorithm. In this workspace, each object is represented by its current position, shape, and estimated velocity. The object’s shape is assumed to be elliptic, and real objects are represented as ellipses. This workspace can be seen as a local map of symbolic objects with their associated estimated static (shape, position) and dynamic (velocity) properties.

Path Planning Module

Various methods based on the CSG representation of obstacles are used for path planning. Each obstacle in the workspace is expressed as a constraint that must be met in the search space (that is, the path must not pass through the obstacle) while minimizing the Euclidean distance from the start point to the target point. The specific method will be introduced in the next section.

Obstacle Avoidance and Path Planning Method

Obstacle avoidance and path planning methods can be divided into two types: global path planning methods and dynamic path planning methods. The global path planning method is suitable for the situation where the global map is known and the obstacles are usually static obstacles. Therefore, from the perspective of practical significance, the dynamic path planning method is more practical.

Global Path Planning Method

Global path planning is a classic optimization problem that can be solved by many optimization algorithms. The complexity of three-dimensional (3D) path planning for autonomous underwater vehicles requires the optimization algorithm to have a quick convergence speed.

Liu et al. (2015) provide a new 3D path planning method for AUV using a modified firefly algorithm. In order to solve the problem of slow convergence of the basic firefly algorithm, an improved method was proposed. In the modified

firefly algorithm, the parameters of the algorithm and the random movement steps can be adjusted according to the operating process. At the same time, an autonomous flight strategy is introduced to avoid instances of invalid flight. An excluding operator was used to improve the effect of obstacle avoidance, and a contracting operator was used to enhance the convergence speed and the smoothness of the path.

Zhang (2006) proposed a genetic algorithm-based hierarchical global path planning method for Autonomous Underwater Vehicles in ocean. The method bases on cell decomposition approach, but it only decomposes the cells which are used in the path planning, so the method can save the memory effectively for the global path planning for AUV in ocean. The genetic algorithm is applied to find the path at each level. Results of the computer simulation are given to show the feasibility of the proposed algorithm.

Dynamic Path Planning Method

The dynamic path planning and obstacle avoidance control algorithm are based on the established ocean map model, and searches for the best reachable path between the planned start point and the target end point under the constraints of sailing time, smooth path, and lowest energy consumption. In the past few years, AUV path planning research has achieved fruitful results, which are mainly divided into four categories: geometric model search algorithm, probability sampling algorithm, artificial potential field algorithm, and artificial intelligence algorithm.

The geometric model search algorithm is a classic path search algorithm, which belongs to the category of discrete optimization planning. The realization process is simple, and the model establishment is strict. It mainly includes Dijkstra algorithm (Solka et al. 1995), A* algorithm (Duchon et al. 2014), D* algorithm (Ferguson and Stentz 2005), D*Lite algorithm (Al-Mutib et al. 2011), FM algorithm (Petres et al. 2005), etc. Dijkstra algorithm uses a greedy strategy, using weighted directed graphs or undirected graphs to solve the single-source shortest path problem. A* algorithm is an efficient search algorithm for the shortest path in a static map. D*

algorithm is a dynamic A* algorithm that can be effective that deals with the path search problem in dynamic environment. FM algorithm has good reliability and convergence and can meet real-time requirements.

Probability sampling algorithms mainly include PRM method (Bohlin and Kavraki 2000) and RRT method (Karaman et al. 2011). The core idea of PRM method is pose space sampling and path search, which can effectively avoid obstacles while achieving accurate pose space modeling. The advantage of RRT algorithm lies in its efficient spatial search ability. The expected distance between the random state point and the tree can be quickly shortened.

The artificial potential field method (Chen et al. 2016) is widely used in the field of real-time obstacle avoidance. It has low requirements for environmental complexity, small calculation volume, and fast search speed, but it needs to integrate other algorithms to enhance the global optimization capability.

The artificial intelligence algorithm is a current research hotspot in path planning. Researchers have evolved a variety of algorithm forms from different perspectives of intelligence (Gigras and Gupta 2012), including particle swarm optimization, ant colony optimization, wolf swarm algorithm, simulated annealing algorithm, genetic algorithm, differential evolution algorithm, artificial nerve Network, etc. The artificial intelligence algorithms play an important role in promoting the solution of AUV path planning in complex and dynamic environments. Compared with other algorithms, they have shown great potential, although they need to be further improved in terms of real-time, robustness, and rigorous theoretical proof. It is still the mainstream direction of future research in this field.

Key Applications

Petillot et al. (2001) have presented here a general framework for performing 2-D obstacle avoidance and path planning for underwater vehicles based on a multibeam forward-looking sonar sensor. The ability of the system has been

demonstrated on real sonar data. The sequence used corresponds to a real trial, and the ability of the system to perform obstacle avoidance is demonstrated. The path planning system generates very smooth paths, can handle complex and changing workspaces, and presents no local minima as it uses a convex representation for the obstacles.

Figure 2 shows the simulation results showing the performance of their proposed algorithm. The starting point is the bottom left corner while the goal point is the top right corner. The vehicle

speed is limited to 5 m/s. The simulated sonar's field of view is defined by the circle. The objects in the field of view and currently used for the path planning process are denoted with crosses (+ sign) while the ones that will be used in the next iteration of the path planning algorithm are denoted with squares.

Sun et al. (2018) propose an optimized fuzzy control algorithm for three-dimensional AUV path planning. Based on the sonar model, it can be used for path planning in the complex underwater environment. First, the path planning is

Obstacle Avoidance Technology for Underwater Vehicle, Fig. 2 Example of a generated path on a simulated workspace. (Petillot et al. 2001)

Obstacle Avoidance Technology for Underwater Vehicle, Fig. 3 3D dynamic fuzzy path planning without optimization. (Sun et al. 2018)

established based on the two sonars arranged on the horizontal plane and vertical plane. On the environment information collected by sonars, the virtual acceleration and velocity of AUV in the three-dimensional space can be obtained through the fuzzy system with the accelerate/brake module which enables AUV to avoid dynamic obstacles automatically. Considering the fuzzy boundary choice has great subjectivity, the generated path cannot guarantee to be optimal. Therefore, in order to deal with the optimal path

problem, two optimized methods are compared to do the optimization of the fuzzy set. Simulation results (shown as Fig. 3) indicate that the proposed method can generate an optimal 3D path under the three-dimensional underwater environment (Sun et al. 2018).

Ma et al. (2018) improve the path planning of AUVs in terms of both the path planning model and the optimization algorithm. The proposed model is comprehensive, which aggregates the length, energy consumption, and collision risk

into the objective function and incorporates the steering window constraint. Based on the model, they develop a nature-inspired ant colony optimization algorithm to search the optimal path. Our algorithm is named alarm pheromone-assisted ant colony system (AP-ACS) since it incorporates the alarm pheromone in addition to the traditional guiding pheromone. The alarm pheromone alerts the ants to infeasible areas, which saves invalid search efforts and, thus, improves the search efficiency. Meanwhile, three heuristic measures are specifically designed to provide additional knowledge to the ants for path planning. In Fig. 4, the comparison between the AP-ACS and the simulation results of the other five path planning methods is shown. The experimental results show that AP-ACS can effectively handle the constraints and outperform the other algorithms in terms of accuracy, efficiency, and stability (Ma et al. 2018).

Ocean Thermal Energy Conversion

Zhen Gao

Norwegian University of Science and Technology, Trondheim, Norway

Definition

Ocean thermal energy conversion (OTEC) is a technology that uses the temperature difference between cooler deep water and warmer shallow or surface seawater to run a heat engine to produce energy, typically electricity.

Ocean Thermal Energy Resource

The ocean thermal energy resource depends strongly on the temperature difference in the ocean and the volume of the seawater in the circulation of the OTEC device for electricity generation. Fig. 1 shows the global distribution of the seawater temperature difference near the surface (20 m below the surface) and at the bottom (1000 m below the surface) of the oceans

(Nihous 2010). As we can see, areas with large temperature difference, in the order of 20–25 °C, are in the tropics around the equator and have the potential to develop OTEC devices. In such areas, the surface water temperature can exceed 25 °C, while the sea temperature at a depth of 1000 m is in the range of 5–10 °C. A minimum 20 °C of temperature difference is needed to run an OTEC cost-effectively (Lewis et al. 2011). The ocean thermal energy resource is estimated to be about 88,000 TWh/year, which is much larger than other ocean energy forms (Pelc and Fujita 2002).

Ocean Thermal Energy Conversion Technology

As compared to other offshore renewable energy technology, such as offshore wind, the OTEC technology is still in the early phase of development. Basically, there are two types of OTEC devices, as shown in Fig. 2 (OTEC Africa 2019). In some situation, a hybrid plant can be used (Charlier and Justus 1993).

In a closed-cycle OTEC plant, the warm seawater is pumped through a heat exchanger (evaporator) to evaporate a secondary working

Ocean Thermal Energy Conversion, Fig. 1 Global distribution of average seawater temperature differences (between 20 m and 1000 m water depths) from World Ocean Atlas 2005 data (Nihous 2010)

Ocean Thermal Energy Conversion, Fig. 2 Illustration of a closed-cycle (left) and an open-cycle (right) OTEC plant (OTEC Africa 2019)

fluid (such as ammonia, propane) in a high-pressure condition to drive a turbine to generate electricity. After that, the vapor is cooled down by the pumped cold seawater through another heat exchanger (condenser) to complete a cycle of fluid-vapor-fluid transform. Since the turbine working fluid is under high pressure, a high turbine efficiency for energy conversion can be achieved. The originally warm and cold water are then discharged back to the sea. In an open-cycle OTEC plant, 1% of the warm seawater is evaporated directly in a vacuum chamber, and the vapor will drive a turbine for electricity generation. After that, the vapor is cooled down by the cold seawater as in a closed-cycle OTEC plant, but it will not return to the circulation. In fact, the vaporized warm seawater is also desalinated due to this process and can be used as fresh water. The originally cold water and most of the warm water will be discharged back to the sea.

It should be noted that the change in temperature of the warm and the cold water in an OTEC plant is not significant, in the order of a few degrees Celsius, and therefore a large amount of water needs to be pumped in order to realize enough electricity generation. The whole process of an OTEC, as a heat engine,

has a thermodynamic efficiency of 1–3% (Wikipedia 2019).

Technological Development and Challenges

There are no commercial OTEC plants for electricity generation yet. A few prototypes have been tested (Kobayashi et al. 2004). Japan, followed by the USA and India, has been the main contributor to the development of OTEC technology since 1970s. A closed-cycle OTEC plant became operational in 1981 on the island of Nauru in Japan, producing 120 kW of electricity, with 90 kW used to power the plant and 30 kW to power one school and other places. In 1993, a 200-kW OTEC plant was completed in Hawaii. In 2002, India tested a 1-MW floating OTEC prototype but had a failure in the deep-sea cold-water pipe. From 2006 to 2013, Makai Ocean Engineering developed an OTEC Heat Exchanger Test Facility with a 100-kW turbine at the Natural Energy Laboratory of Hawaii.

In addition to the issues related to maintenance of the vacuum and biofouling and corrosion of heat exchangers, the big challenge for an OTEC is related to the cold-water pipe (Lewis

Ocean Thermal Energy Conversion, Fig. 3 Principle of an OTEC plant and its by-products (Wikipedia 2019)

et al. 2011). OTEC plant can be shore-based or floating at the sea. In all cases, a long pipe is needed to reach the cold water in deep sea, in the order of 1000 m deep. The long pipe will be subjected to current and wave loads, which makes cost higher and design more challenging, especially for a floating OTEC plant.

As of today, it is still too expensive to use an OTEC for commercial electricity generation. However, there are many by-products that an OTEC can produce, including desalinated water for drinking or irrigation and cold water for mariculture, refrigeration, and air-conditioning, as shown in Fig. 3 (Wikipedia 2019). An OTEC plan might be used to produce hydrogen, lithium, and other rare elements. These can improve the economic feasibility of OTEC plant.

Offshore In Situ Penetrometers

Yue Yan
State Key Laboratory of Hydraulic Engineering
Simulation and Safety, Tianjin University,
Tianjin, China

Definition

The offshore in-situ penetrometer is a specially designed device suitable for geotechnical site investigation. It is commonly used in the in-situ testing such as penetration and shearing testing, aiming to characterize the soil properties, thus

capturing the engineering parameters for practice design.

Classification According to Probe Geometry

Cone Penetrometers

The cone penetrometer (Fig. 1a), particularly piezocone, is now regarded the most performed offshore test (occupying more than 95%) during a geotechnical investigation (Lunne 2001). The standard piezocone is a cylindrical penetrometer with a 35.7 mm diameter (projected area of 1000 mm²) 60° conical tip. However, for the seabed site investigation, cone penetrometer with a 43.8 mm conical diameter (projected area of 1500 mm²) is increasingly used. In the area where the properties of shallow sediments are important, cone penetrometers with an 11.3 mm conical diameter (projected area of 100 mm²) are also deployed to provide a sensitive measurement of the upper few meters of the seabed (Lunne 2001). A load cell is attached to the conical tip, measuring the penetration resistance, which is normally termed as q_c (kPa). A sleeve is mounted above the tip and a load cell attached to this sleeve, measuring the side friction termed as f_s (kPa). The importance of penetration pore pressure measurement for the interpretation of cone penetration test (CPTU) has been increasingly acknowledged, and therefore almost all offshore cone penetrometers allow the simultaneous measurement of pore pressure, cone resistance, and sleeve friction. This means the pore pressure transducers are mounted at least at one position: face of the cone (so-called u_1 position), on the shoulder (just above the tip – u_2) or above the sleeve (u_3).

The cone penetrometer provides a continuous measurement of soil profile with depth, and therefore is extremely useful in detecting the fine change in soil stratigraphy and soil behavioral classification (Robertson 1990). A number of correlations of the soil parameters and measurement have also been established for different types of soil (e.g., the normalized cone response with the relative density D_r for silica sands; the net cone

Offshore In Situ Penetrometers, Fig. 1 Typical penetrometers used offshore

resistance with the shear strength profile by means of a cone factor N_{kt} for fine-grained sediments).

Due to the high ambient water pressure, a high capacity load cell is often required. However, this affects the measurement sensitivity in detecting small changes in resistance in soft sediments

from CPTU. Also, the measurement accuracy is hindered due to the required measurement corrections on the cone resistance for the unequal area effect and overburden stress. These limitations have led to the introduction of the full-flow penetrometers to provide reliable soft soil characterization at deep water sites.

Full-Flow T-Bar and Ball Penetrometers

The T-bar penetrometer (Fig. 1b) introduced at the University of Western Australia was the first full-flow penetrometer, which consists of a cylindrical bar attached to the penetrometer rods. It was originally designed to improve the accuracy of strength profiling in centrifuge modeling (Stewart and Randolph 1994), and was later scaled up to be used offshore in the late 1990s (Randolph et al. 1998). For field use, a standard T-bar dimensions of 40 mm diameter by 250 mm long is recommended. And the cylinder should have a minimum length to diameter ratio of 4, and the connecting shaft should be no more than 15% of the projected area of the T-bar. With the large protrusion of the cylindrical bar compared to the shaft, the T-bar penetrometer is more susceptible to eccentric loading. The piezoball (Fig. 1c) penetrometer has been therefore proposed. The piezoball penetrometer normally includes a ball with a diameter varying between 50 and 120 mm, with the shaft (no more than 15% of the projected area of the ball) mounted just behind the ball. Pore pressure sensors are mounted either at the mid-depth or at discrete points on the lower half of the ball.

The main advantages of the full-flow penetrometers over the cone penetrometer include (Randolph et al. 2007): (1) the load cell measures a net pressure on the bar, and therefore no correction to the effect of overburden stress is required; (2) the projected area of the full-flow penetrometer is normally 10 times of the cone, and this reduces the sensitivity to any load cell drift if the same load cell is used; (3) the exact plasticity solution has been presented to correlate the measured net pressure with the shear strength; (4) the remolded shear strength can be assessed using cyclic penetration and extraction test over short depth intervals (typically less than 0.5 m).

Vane Shear

The vane shear is conventional in situ test, as to measure the peak and residual shear strength for soft sediments. Generally, three different sizes of vane are used offshore, all with a height to width ratio of two and with the height ranging between

80 mm and 130 mm (NORSOK Standard 2004). The size of vane is chosen according to the localized strength of the soil to be investigated. In offshore condition, the measurement to the residual shear strength using vane shear is less attempting than that under onshore condition, as the offshore downhole tool or seabed frame limits the upper rotation speed and angle, which affects the robustness of the measurement.

Specialized Penetrometers

Lunne (2001) summarized a number of more specialized tests that may be undertaken, which includes:

- Seismic piezocone tests, to obtain profiles of small strain shear modulus G_0
- Cone pressuremeter tests, with a cylindrical expansion pressuremeter situated just behind the cone, with the primary aim of measuring unload–reload shear modulus
- Electrical resistivity (in sand) and nuclear density probes, both of which provide an estimate of the soil density
- Piezometer probe (or piezoprobe), to determine the ambient pore pressure

More specific tests are also undertaken aimed at a particular foundation or pipeline option in order to validate design parameters or a construction procedure, which include:

- Plate load tests, generally conducted at the seabed
- Hydraulic fracture tests
- Open hole stability tests
- Grouted section tests
- SMARTPIPE facility
- Toroid and hemi-ball penetrometers

Installation and Testing Technology

Work Platform

The platform is most expensive component in the field of site investigation. The selection of the appropriate platform relies on the careful weighing up between the economy efficiency

and the working ability. The recommendation in the different water depths at the site include:

1. Diver operated from a support vessel or barge (water depth < 20 m)
2. Jack-up rig (20 m < water depth < 200 m)
3. Remote equipment from a support vessel (all water depths, depending on vessel draft)
4. Anchored drilling vessel (20 m < water depth < 200 m)
5. Specialized dynamically positioned (DP) vessels (for deepwater locations)
6. Remotely operated equipment, supported by construction vessels or small DP vessels

Installation Type

The geotechnical site investigation is performed by a specialized penetrometer from a purpose-built system (a downhole system and alternatively, a seabed system).

Both systems can be used for CPT, T-bar, ball penetrometers, and vane shear. But the seabed system intrudes less investigation depth than the downhole system and is also disadvantaged when a hard layer is present. Therefore, the seabed system is more appropriate for the deepwater site investigation, where the sediments within the depth up to 20–50 m is most of interest.

Testing Procedure

Conducting cone penetration tests in the offshore condition follows the International Reference Test Procedure (IRTP) published by the International Society for Soil Mechanics and Geotechnical Engineering (ISSMGE) (1999) and various national and international standards such as NORSOK Standard (2004), ASTM D5778-07 (2007), and ENISO 22476-1 (2007). The standard rate of penetration is 20 mm/s, or approximately half a diameter per second. Lunne et al. (1997) provides a detailed introduction about the cone penetration testing, including both equipment and interpretation.

Standard practice for full-flow penetrometers in the site investigation has not been published, but the following principles are generally agreed:

The penetration and extraction rate should be in the range of 0.2–0.5 diameters per second, and at least one cyclic penetration and extraction test is

recommended within each penetration test in order to correct the load cell offset if necessary, and assess the penetration resistance for remolded conditions. Specific tests may also be involved, using different rates of penetration in order to evaluate strain-rate and consolidation characteristics of penetration resistance.

The vane is thrust into the soil by a minimum distance of 0.5 m and rotated at a speed of 0.1 or 0.2 °/s, and additional tests may be required by pushing the vane deeper recommended by at least 0.5 m. Under the onshore condition, the remolded shear strength can be achieved by rotating the vane rapidly for ten revolutions, and then reverted to the original test speed to obtain a remolded strength. However, the offshore equipment involved a down-hole tool or a seabed frame, thus limiting the upper speed to less than 1°/s. A test of 20 min is typical to obtain the peak strength and remolded strength (Peuchen and Mayne 2007). The vane is competent in giving a reliable assessment of the localised shear strength. However, it is unable to present a continuous profiling of the site, or providing information about soil classification. It is therefore less attempting to use vane shear test to assess the resistance compared to the other penetrometers.

Assessment of Soil Properties

Soil Type Characterization

Measurement of the friction from the cone penetrometer along the sleeve and the pore pressure close to the tip provides information from which the type of soil may be assessed through correlations. Normalized parameters are used for such classification, principally:

- Normalized cone tip resistance, $Q = q_{\text{net}}/\sigma'_{v0}$
- Excess pore pressure ratio, $B_q = \Delta u_2/q_{\text{net}}$
- Friction ratio, $F_r = f_s/q_{\text{net}}$

Generally, the classification charts show that stronger soils (dense sands or cemented sediments) correspond to higher normalized cone resistance, Q , and low friction ratio, F_r , compared with clays (Robertson 1990). The data may be distorted due to the effects of increasing over-

consolidation ratio or increasing degree of drainage for silty soils, which both lead to increasing Q , but decreasing B_q . And by considering the excess pore pressure ratio, $\Delta u_2/\sigma'_{v0}$, the modified charts are able to separate the trends again (Schneider et al. 2008).

Interpretation in Sands (Free Drainage Sediments)

For the silica sands, the major correlations are for the relative density D_r and the state parameter ψ (Been and Jefferies 1985). The correlation of relative density may be correlated with normalized cone resistance $Q = q_{net}/p'_0$ where p'_0 is the in situ mean effective stress as:

$$D_r = \frac{1}{C_2} \lambda \ln \left(\frac{1}{C_0} \frac{q_c}{p'_0} \left(\frac{p'_0}{p_a} \right)^{1-C_1} \right) \quad (1)$$

where p_a is atmospheric pressure, and the various parameters are usually taken as, $C_0 = 25$, $C_1 = 0.46$, $C_2 = 2.96$.

Note for the more compressible (still free draining) sediments, such as carbonate sands, much lower normalized cone resistances are given unless cemented.

The cone penetration tests are increasingly preferred as a design method for the driven piles in sand by the American Petroleum Institute (API) and International Standards Organisation (ISO). And cone penetration test is also regarded as a model test for the shallow foundation design (Randolph et al. 2004).

Interpretation in Clays

Undrained Cone Penetration

The cone penetration in fine-grained sediments can be regarded as undrained behaviours, and the interpretation of cone test mainly focused on assessing the shear strength profile by cone factor N_{kt} ,

$$s_u = \frac{q_t - \sigma_{v0}}{N_{kt}} = \frac{q_{net}}{N_{kt}} \quad (2)$$

As the cone factors range widely (Lunne et al. 1997) depending on the soil characteristics, industry practice recommends calibrating the cone

resistance at each site against laboratory strength measurements.

For the ease of use, theoretical solutions relate N_{kt} with the rigidity index $I_r = G/s_u$, a stress anisotropy factor $\Delta = (\sigma'_{v0} - \sigma'_{h0})/2s_u$, and friction ratio on the cone face $\alpha_c = \tau_f/s_u$:

$$N_{kt} \approx C_1 + C_2 \ln(I_r) - C_3 \Delta + C_4 \alpha_c \quad (3)$$

And the values for the various constants are given by Teh and Houlsby (1991).

Undrained T-Bar/Ball Penetration

Strictly, the correction to the net resistance is also required for the full-flow penetrometers. However, it is often regarded sufficient to ignore such correction, due to the large projected area of the penetrometer relative to the shaft.

Similar to the cone penetration test, the shear strength profile may be estimated from a T-bar or ball penetration by means of a penetrometer factor $N_{k,Tbar}$ or $N_{k,ball}$. The factor $N_{k,Tbar}$ is originally recommended taken as 10.5, based on a plasticity solution for a cylinder moving laterally through the soil (Randolph and Houlsby 1984; Martin and Randolph 2006). The refined analyses consider strain rate hardening, remolding, and the soil conditions of offshore sites, which leads to minor adjusted recommended values. Theoretical resistance factors for the ball penetrometers are around 20–25% greater than that for the cylindrical T-bar (Randolph et al. 2000), but the field and laboratory data indicates much closer resistances (Chung and Randolph 2004).

Cyclic penetration and extraction tests allow assessment of the remolded shear strength, and this often requires a load cell zero correction (Randolph et al. 2007).

Vane Shear Test

Interpretation of the vane shear test follows the classical relationship between torque and undrained shear strength by:

$$s_u = \frac{T}{\frac{\pi d^3}{6} (1 + 3 \frac{h}{d})} \quad (4)$$

The measured strength in a vane shear test is sensitive to the precise testing procedure,

especially the delay between insertion and testing, and the rotation rate (Chandler 1988). However, the current practice recommends no correction factors to offshore vane strength, as the different factors compensate each other to some extent (Quirós and Young 1988).

Pore Pressure Measurement and Consolidation Characteristics

Cone Test

The filter positioned at the shoulder of the cone provides the pore pressure measurement during a cone test. The measured dissipation response may be fit to the theoretical solutions (e.g., Teh and Houlsby 1991), as to derive a consolidation coefficient. It is argued that the soil close to the cone may undergo consolidating, but the major part of the surrounding soil undergo swelling, and therefore the derived coefficient reflects both the horizontal flow paths and the swelling nature of the strain path (Levadoux and Baligh 1986). The dissipation tests in clay may require 1–3 h for the T_{50} to be reached, and this is very expensive in the offshore condition. In siltier sediments, the test requires much shorter duration. The derived consolidation coefficient also helps to determine whether the cone penetration itself is an undrained process and the cone penetration resistance is affected by the partial consolidation (Randolph and Hope 2004).

T-Bar and Ball Penetrometers

The pore pressure sensors may also be built into both T-bar and ball penetrometers (Kelleher and Randolph 2005; Low et al. 2007). And the piezoball penetrometer is a more efficient device compared to the piezocone penetrometer to detect the consolidation coefficient in the field condition, if the same diameter is adopted for both penetrometers.

Definition

Pile driving is the process of installing a pile into the seabed in order to support or anchor super structures.

Introductions

Pile driving system includes the hydraulic hammer hanging on a crane hook and the pile (shown in Fig. 1). Open-ended piles are widely used in many engineering applications, especially for offshore and near-shore engineering, such as jacket platforms, mooring systems, offshore wind turbines (Fig. 2). The advantages of onshore applications of piles are well recognized, in particular because of the short installation time and low installation cost.

The driveability of the open-ended piles is influenced significantly by the soil resistance during the driving (SRD), which is generally attributed to the outer skin resistance, inner skin resistance, and bearing resistance. The soil plug may influence the SRD. During the driving, the penetration velocity will also influence the SRD. There are also many issues during the pile installation, including premature pile refusal and pile running during the driving process (Yan et al. 2012; Guo and Shao-Lin 2011; Randolph 2003a; Dover and Davidson 2007). The work is to summarize the study outcomes on pile driving and calculation method, including pile driving formula, the penetration resistance, and the pile running and premature refusal analysis.

Pile Driving Formula

The vibratory driving technique such as jacking and impact driving is widely used in offshore and near-shore engineering. Pile driving formula is

Offshore Pile Driving,

(c) mooring piles

Offshore Pile Driving, Fig. 2 Piles used in Jacket platform, offshore wind turbines, and mooring systems. (a) Jacket platform. (b) offshore wind turbines. (c) mooring piles

used for designing the driving and determining the pile capacity. Pile driving formulas can be written mathematically as (Olson and Flaate 1967):

$$e_h W_H h = Q_u (s + s_c) \quad (1)$$

where W_H is the hammer (ram) weight; h is the hammer drop height; e_h is the hammer efficiency; Q_u is the ultimate pile capacity; s is the observed pile set; and s_c is an empirical constant expressing the aforementioned energy losses and the energy stored temporarily inside the pile due to elastic compression during the blow process.

There are a large variety of pile driving formulas available in the literature; they are summarized in Table 1.

Hiley Formula (1925): Q_u = the ultimate load, W_H = Weight of Hammer, W_P = weight of pile, C_1 = temporary compression in packing helmet, C_2 = temporary compression of pile, C_3 = temporary compression of ground at toe (often

referred as quake), s = pile penetration for last blow, also called “set,” e = coefficient of restitution.

The pile driving formulas summarized above usually used in specific deposit that verified through the experiment.

Penetration Resistance During Pile Driving

Soil Plug During Pile Driving

The contribution of the plug capacity to the SRD is very significant if the pile is plugged during driving, either partially or fully. When the pile is plugged during driving, the end bearing is not limited to the frictional resistance developed by the soil plug for SRD calculations (Randolph et al. 1991). To study the effect of plugging on the SRD, it is necessary to measure the movement of the soil plug. Therefore, it is important to quantify the

Offshore Pile Driving, Table 1 Summary of pile driving formulas

Formula	Equations	Notes
Danish Formula(Olson and Flaate 1967)	$Q_u = \frac{e_h E_h}{s + \sqrt{(e_h E_h L_{2AE})}}$	e_h = hammer efficiency E_h = the rated hammer energy E = modulus of elasticity of pile materials L = length of piles A = area of pile cross section
Hiley Formula(Hiley 1925)	$Q_u = \frac{\eta e_h E_h}{s + \frac{C}{2}} + W_H + P$	$C = C_1 + C_2 + C_3$ $\eta = \frac{(W_H + e^2 W_P)}{(W_H + W_P)}$
Janbu Formula (Janbu 1953)	$Q_u = \frac{e_h E_h}{K_u s}$	$K_u = C_d \left[1 + \left(1 + \frac{\lambda_e}{C_d} \right)^{0.5} \right]$ $C_d = 0.75 + 0.15 \frac{W_P}{W_H}$ $\lambda_e = \frac{e_h E_h L}{AE s^2}$
Dutch Formula (Whitaker 1976)	$Q_u = \frac{e_h E_h}{s + a W_P / W_H}$	$a = s$ for drop hammers and 0.1 for steam hammers
Gates Formula (Gates 1957)	$Q_u = a \sqrt{(e_h E_h)} (b - \log s)$	$e_h = 0.75$ for drop hammer s = rated hammer energy $a = 104.5, b = 2.4$
Modified ENR (ENR 1965)	$Q_u = \left(\frac{1.25 e_h E_h}{s + C} \right) \left(\frac{W_H + n^2 W_P}{W_H + W_P} \right)$	$C = 0.0025 \text{ m}$ $n = 0.5$ for steel-on-steel anvil on steel or concrete piles
PCUBC formula (Hiley 1925)	$Q_u = \left(\frac{e_h E_h W_H + K W_P}{s + \frac{Q_H L}{AE}} \right)$	$K = 0.25$ for steel piles and 0.1 for all other piles

degree of plugging which can be done by measuring the Incremental Filling Ratio (IFR) during driving. The degree of plugging can be quantified by IFR defined as,

$$IFR = \frac{\Delta L_s}{\Delta D} \times 100\% \quad (2)$$

where ΔL_s is the unit increment of the soil plug length corresponding to a unit increment of pile penetration depth (ΔD). The fully plugged and fully coring modes are then represented as IFR = 0 and 100%, respectively. A value of IFR between 0% and 100% means that the pile is partially plugged. (Paik and Salgado 2003a) IFR is linked to the hammer impact characteristics such as input energy and pile diameter. (Brucy et al. 1991).

The degree of soil plugging can be quantified using the plug length ratio (PLR) and IFR. The PLR is defined as:

$$PLR = \frac{L_s}{H} \quad (3)$$

where L_s = the soil plug length (m), H = penetration depth of pile (m).

The relation between IFR and PLR can be defined as $IFR(\%) = a \times PLR + b$ (Jeong et al. 2015). Many researchers studied the relationship between IFR and PLR (Jeong et al. 2015; Murthya et al. 2018; Paik and Salgado 2003b; Xie et al. 2005; Fattah et al. 2016), a and b are also established though model test (Szechy 1959; Klos and Tejchman 1977), shown in Fig. 3.

Penetration Resistance Calculation

The penetration of an open-ended pile consists of three components during driving, including tip resistance, outer skin resistance, and plug resistance (Kumara et al. 2016) which is can be defined as:

$$Q_u = Q_{an} + Q_{out} + Q_{plug} \quad (4)$$

$$Q_{plug} = \min(Q_{in}, Q_b) \quad (5)$$

Offshore Pile Driving, Fig. 3 Relationship between IFR and PLR

where Q_u is ultimate bearing capacity, Q_{an} is annulus resistance, Q_{out} is outer frictional resistance, Q_{plug} is plug resistance, Q_{in} is inner frictional resistance, and Q_b is base resistance.

In the calculation of ultimate bearing capacity, the inner friction resistance is more complex than the end resistance and lateral friction resistance due to the internal earth plug.

According to Paikowsky (1990) arching occurs within a soil plug under static loading, which leads to high internal friction.

The soil plugging index (SPI) is defined as:

$$SPI = \frac{L_{is}}{L_s} \times 100 \quad (6)$$

where L_s is the soil plug length and L_{is} is the length of the developing inner skin friction. According to Sangseom Jeong et al. (2015) the soil plugging index (SPI) based on the combined test results is expressed as $SPI = -0.03D_i + 43.2$, where D_i is the inner pile diameter (mm).

The proposed SPI is a function of the inner pile diameter. The length of mobilizing inner skin friction is obtained as follows:

$$L_{is} = \frac{L_s \times SPI}{100} \quad (7)$$

The actually mobilizing inner skin friction can be obtained by using the obtained L_{is} .

$$Q_{si} = f_{si} \times A_{si} = f_{si} \times \pi D_i L_{is} \quad (8)$$

where Q_{si} is the actually mobilizing inner skin friction, f_{si} is the unit inner skin friction, A_{si} is the area of the mobilizing inner skin friction, and D_i is the inner pile diameter (Jeong et al. 2015).

In the practice, the open-ended pile will have a completely occlusion effect and partially occlusion effect, and the bearing capacity formula of the completely plugged pile can be calculated as (Yan et al. 2011):

$$Q_u = \eta q_u A_0$$

$$\eta = \begin{cases} 0.490.65 & \text{Clay} \\ 0.49 & \text{Silt} \\ 0.49 & \text{Sand} \end{cases} \quad (9)$$

$$q_u = 1.3cN_c + \gamma_1 DN_q + 0.6\gamma RN_r$$

$$\gamma_1 = \gamma + 2 \frac{f_s + n\tau}{(n^2 - 1)R}$$

where η is Dynamic effect coefficients, R is the inner radius of the pile, and γ_1 is the equivalent unit weight of soil above the pile tip. γ is the unit weight of the soil above the pile tip, f_s is the ultimate raft friction, and τ is the shear strength of the soil above the pile tip.

By the survey data of CPT method, the calculation method of the bearing capacity of pipe piles with complete and incompletely occlusion was summarized (Lehane et al. 2005) and the calculation of pile tip resistance in the case of complete occlusion is as follows:

$$\begin{aligned} Q_b &= q_{b0.1} \frac{\pi}{4} D^2 \\ \frac{q_{b0.1}}{q_c} &= 0.6 \end{aligned} \quad (10)$$

where q_c is average CPT end resistance, $q_{b0.1}$ is the pile end bearing resistance at a pile base movement of 10% of the pile diameter, and D is the pile diameters.

Under the condition of partially occlusion, the pile end bearing is calculated as follows:

$$\begin{aligned} Q_b &= q_{b0.1} \frac{\pi}{4} D^2 \\ \frac{q_{b0.1}}{q_c} &= 0.15 + 0.45 \times A_{rb}^* \\ A_{rb}^* &= 1 - FFR \left(\frac{D_i^2}{D^2} \right) \\ FFR &= \min \left\{ 1, \left[\frac{D_i(m)}{1.5m} \right]^{0.2} \right\} \end{aligned} \quad (11)$$

where D_i is Inner Diameter, A_{rb}^* is the effective area ratio, the other parameters as same as 10 equation. And the skin resistance is calculated as follows:

$$\begin{aligned} Q_s &= \pi D \int \tau_f dz \\ \tau_f &= \sigma'_{rf} \tan \delta_{cv} = \frac{f}{f_c} (\sigma'_{rc} + \Delta \sigma'_{rd}) \tan \delta_{cv} \\ \sigma'_{rc} &= 0.03 \cdot q_c (A_{rs}^*)^{0.3} \left[\max \left(\frac{h}{D}, 2 \right) \right]^{-0.5} \\ A_{rs}^* &= 1 - IFR_{\text{mean}} \left(\frac{D_i^2}{D^2} \right) \\ IFR_{\text{mean}} &= \max \left[1, \left(\frac{D_i(m)}{1.5m} \right)^{0.2} \right] \\ \Delta \sigma'_{rd} &= 4G \frac{\Delta r}{D} \text{ with } G = q_c \cdot 185 \cdot q_{c1N}^{-0.7} \text{ and} \\ q_{c1N} &= (q_c / p_{atm}) / (\sigma'_{vo} / p_{atm})^{0.5} \end{aligned} \quad (12)$$

where δ_{cv} is constant volume interface friction angle, σ'_{rf} is radial effective stress at failure, σ'_{rc} is radial effective stress after installation and equalization, $\Delta \sigma'_{rd}$ is increase in radial stress due to loading stress path (dilation), f/f_c is 1 for compression loading and 0.75 in tension, IFR_{mean} is

the average IFR measured over the final 20 diameters of penetrations, G is operational shear modulus (assumed equal to the in-situ very small strain value), Δr is interface dilation (assumed = 0.02 mm for the database), and p_{atm} is a reference stress = 100 kPa.

Velocity-Dependent Penetration Resistance

The strength behavior of soils can be significantly affected by the applied rate of loading, which is very important for the design of pile bearing capacity. Some new methods such as Cone Penetration Test (CPT) have been in popular use considering the speed of pile penetration into the ground and the relative velocity of the pile with respect to the surrounding soil.

A parameter R_f was adopted to describe the effect of velocity on soil strength (Chow et al. 2015), which can be expressed as:

$$R_f = \left[n \frac{v/d}{(v/d)_{ref}} \right]^\beta \quad (13)$$

where v_{ref} is a reference velocity equal to the penetration rate adopted in the measurement of $s_{u(CPT)}$, d is the FFP diameter, n is introduced to account for the greater rate effects reported for shaft resistance compared to tip resistance, and β is a strain rate parameter.

The bearing and frictional resistances were scaled by a rate function R_f and assumed that at any given location the operational strain rate may be approximated by the normalized velocity (O'Loughlin et al. 2013). R_f can be expressed as:

$$\begin{aligned} R_f &= 1 + \lambda \log \left[\frac{v/d}{(v/d)_{ref}} \right] \quad \text{or} \quad R_f \\ &= \left[\frac{v/d}{(v/d)_{ref}} \right]^\beta \end{aligned} \quad (14)$$

where λ and β are strain-rate parameters and v is velocity of penetration in static penetration tests.

The effect of shear rate on measured vane shear strength was studied (Sharifounnasab and Ullrich 1985) and the relevant formula is:

$$\frac{s_v}{s_{v0}} = \alpha \left(\frac{\omega}{\omega_0} \right)^\beta \quad (15)$$

in which s_v is vertical shear strength; s_{v0} is vertical shear strength, measured at the standard shear rate; ω is shear rate; ω_0 is standard shear rate; and α and β are coefficients which depend on the properties of the soil.

The majority of dynamic pile tests are analyzed using pile–soil interaction models based on Smith (1960), (Randolph 2003b) with the soil resistance expressed as:

$$\tau_d = \text{Min} \left(1, \frac{w_p}{Q} \right)^\beta (1 + Jv) \tau_s \quad (16)$$

where w_p is the local pile displacement, τ_d and τ_s are the dynamic and static shaft friction values, Q is the displacement, or “quake,” to mobilize the limiting static resistance, and J is a damping parameter multiplying the local pile velocity, v .

American Petroleum Institute (API) does not provide guidelines for the effects of cyclic loading and rate of loading on the axial capacity of piles. (Iskander 2010) There is evidence that cyclic tensile loading, in particular, may significantly reduce pile capacity (Kraftjr 1990).

Thus, it can be seen the velocity do have a significant effect on the properties of soil which cannot be ignored and more research needs to be further developed.

Refusal and Pile Running During the Driving

Pile is an important part of offshore platform structure. The materials and operations of construction have a significant impact on the cost of offshore projects. It has proved that there are certain risks in the construction of pile and may cause some serious problems during the operation, such as pile driving refusal and pile running. With the development of offshore platforms into deep water and large scale, the impact of such kind of risks is even more prominent. Therefore, it is necessary to have a good understanding of the

causes of these risks from the technical perspective and present the preventive methods and measures in the design and construction.

Pile Driving Refusal

Super long piles with large diameters usually have to be manufactured by segments before installation because of transportation and hoisting difficulties. The segments of the pile will be assembled by welding to the formerly penetrated one. The assembling work often takes 1 day or even a longer time. In additional, the construction process may pause due to other various problems which will take a long time to restart the driving (Yan et al. 2012).

During this period of time, the excess pore pressure in the soil below and around the pile, which is built up during pile driving, will dissipate to some extent, increase the strength of the soil, and make restarting the successive penetration very difficult, sometimes even refusal may take place. This matter has been encountered quite often in many engineering cases and puzzled the designers for years. As for the pile driving refusal, many experts have conducted extensive research and made a series of achievements.

Based on the platform WHPE in Bohai Gulf, Yan et al. (2012) proposed several measures to reduce the refusal risk for restarting a segmented pile:

1. Cutting down the pile extension time is the most effective measure to minimize the refusal risk.
2. To keep the pile tip in a clay layer instead of in the sand layer when extending the pile segment.
3. When the stick-up stability was satisfied, increasing the length of the last segment of the pile and assembling the pile segments when the pile tip penetrates into a clay layer could greatly ease the difficulty of driving the pile.

The reasons of piling refusal in the restarting process were analyzed and presented a numerical method for judging the risk of refusal by estimating the blow counts after pile extension, in which

the regain of soil strength is considered (Yan et al. 2015a). A fatigue factor β , which can be expressed as the following formula, is consistently introduced to cover all reasons and associated with the degree of consolidation.

$$\beta = \begin{cases} \left(\frac{X}{Y-5}\right)^2, & X \leq Y - 5 \\ 1, & Y - 5 < X \leq Y \end{cases} \quad (17)$$

where Y is the designed penetration and X is the specified pile tip penetration. In order to predict if refusal may occur at any restart penetration after pile extension, blow counts needed to penetrate the pile for further 30 cm are estimated. If the estimated blow counts less than an acceptable value, refusal is considered not to take place at this penetration.

A case of a practical offshore pile installation which experienced refusal is analyzed (Sa et al. 2013). Empirical equations are provided to predict soil resistance during driving and after setup. According to the research results of Skov and Denver (1988), the empirical relationship to estimate the time effect on the resistance which helps to analyze bearing capacity can be expressed as:

$$\frac{Q_t}{Q_0} = 1 + A \left[\log \left(\frac{t}{t_0} \right) \right] \quad (18)$$

where the soil resistance corresponding to finishing one pile section is denoted as Q_0 while Q_t represents the soil resistance after a suspension of time t . A and t_0 are two empirical parameters depending on the soil properties.

Characteristics of local soil around the pile are summarized though comparing the resistance changes between local geologic data and pile driving record data (Pu 2012). Result shows that the soil resistance within a period of time after driving is much higher than that in the process of pile driving. Based on the driving records, the back-figured method is applied to estimate the pile bearing capacity after refusal taking place. The required equipment, key technology, and main technological processes in the installation process of the shallow water jacket after pile refusing were described (Hui and Wang 2014).

The researches relevant to the driving refusal mainly focused on the mechanism and some measures based on the practical engineering or simulation software, which can provide the references and analytical analysis to the design and construction of practical project. Some more flexible and economic measures need further study.

Pile Running

Offshore platforms in deep seas require extremely long large diameter pipe piles (LDPPs) to support the loads generated from the structure itself, wind and waves. If the LDPPs are in two or more segments, in situ pile splicing is required, which requires additional construction time and leads to premature refusal. One solution to this problem is to use a single segment of LDPP and drive it continuously into the seabed. As the LDPP could be very heavy (700 t or more), pile running may occur (Randolph 2003a; Dover and Davidson 2007; Olson and Flaate 1967). The unexpected pile running may break the steel wire or even cause the hammer to be lost in the sea.

The researches relevant to the pile running are mainly engaged in the predicting procedure based on the energy conservation method or critical equilibrium conditions.

Yan et al. (2015b) proposed a procedure for predicting the pile-running zones based on the limit equilibrium of pile weight and soil resistance. The total soil resistance can be expressed as:

$$Q_d = Q_f + Q_p = \bar{f} A_s q_u A \quad (19)$$

where Q_d is the total soil resistance, Q_f is shaft resistance, Q_p is the bearing capacity of the pile sand, $\bar{f}$ is the average frictional force per unit area, q_u is the bearing capacity of the pile end, and A is the area of the annular pile end. Pile-running may occur if the following conditions are satisfied:

$$Q_d \leq W_P \quad \text{or} \quad Q_d \leq W_P + W_H \quad (20)$$

In which W_H is the hammer weight and W_P is the weight of the pile. The equilibrium conditions above belong to different states. Yan et al. (2016) also established a predicting procedure based on

the energy conservation method of the running pile. The key theoretical formula can be expressed as:

$$E_G = W_r + E_s \quad (21)$$

where E_G is the potential energy of pile hammer, W_r is the work done by lateral friction resistance and the tip resistance, and E_s is the consume energy.

Sun et al. (2016) proposed an analytical method to predict the occurrence of pile running and established the framework for determining the calculation parameters from a laboratory or field test. The process can be separated into two phases: (1) the energy transfers from the hammer to the pilehammer system and (2) the pile and hammer sink together into the soil embedment, which can be, respectively, expressed as the following formulas:

$$\eta_b m_h g h_p = \frac{1}{2} (m_h + m_p) v_0^2 \quad (22)$$

$$\begin{aligned} \frac{1}{2} (m_h + m_p) (v_j^2 - v_{j-1}^2) \\ = (W - F_s - F_t - F_b) \Delta S \end{aligned} \quad (23)$$

where m_h is the mass of the ram (unit in kg); g is the gravitational constant; h_p is the stroke of the hammer; m_p is the total mass of the LDPP, anvil, helmet, and follower with units in kg; v_0 is the instantaneous velocity of the hammer and pile at the time immediately after the impact; and η_b is the efficiency of the blow. Sun et al. (2017) also proposed a simplified theoretical method to explain the mechanisms of the pile running and proposed a factor of friction degradation to calculate the dynamic skin friction from the static ultimate skin friction of surrounding soil to predict the pile running condition. Based on the force equilibrium on the vertical direction, the resultant force F could be derived as:

$$F = W - Q_f - Q_p - F_b \quad (24)$$

where W is the effective self-weight of the LDPP and hydraulic hammer, Q_f is the side skin friction,

Q_p is the end bearing resistance, and the F_b is Buoyant weight of the displaced soil. The LDPP driven can be analyzed by this formula.

Conclusions

The driveability of the open-ended piles is influenced significantly by the soil resistance during the driving (SRD); SRD consists of the outer skin resistance, inner skin resistance, and bearing resistance. The soil plug has a great influence to the SRD. The soil strength is dependent on the penetration velocity; during the driving, the penetration velocity will also influence the SRD. Based on the influence factor, the calculation method of the penetration resistant is summarized, the judgment approach of the pile running and premature pile refusal are also summarized.

Accidental loads; Ice loads; Offshore structure;
Plastic design; Ultimate strength

Definition

Offshore structure is an installation of structures in a marine environment with relative far distance to nearest shore, usually for the production and transmission of electricity, oil, gas, and other resources. Typical offshore structures are subsea oil and gas developments, offshore platforms (fixed platforms, semi-submersibles, spars, tension leg platforms, floating production storage, and offloading), offshore wind turbines, and subsea pipelines. Depending on the loading conditions, offshore structures can be made of steel, concrete, or composite materials. **Ice loads** are referring to the loads exerted to *offshore structures* from various ice types, such as first-year level ice, multi-year level ice, ice ridge, brash ice, and iceberg. The main focus of this section is the design methodology used for the design of *offshore structure under ice loads*.

Scientific Fundamentals

Limit State Design Principles

The offshore structures shall be designed in a way that it can sustain all possible loads during their lifetime without causing human loss and significant economic or environmental pollutions. The designers are encouraged to check the conditions that may lead to structure failure, which are referred as limit states. Following limit states are

defined for offshore structure design under ice actions (ISO19906 2010):

- Ultimate limit state (ULS) that generally corresponds to resistance to extreme-level ice event (ELIE), both local and global actions shall be considered.
- Serviceability limit state (SLS) that corresponds to criteria governing normal functional use under serviceability-level ice event (SLIE).
- Fatigue limit state (FLS) that corresponds to the accumulated effect of repetitive actions.
- Accidental limit state (ALS) that corresponds to accidental events and abnormal-level ice event (ALIE), both local and global actions shall be considered.

Generally, the offshore structure shall be designed to comply the criteria corresponding to all of the above defined limit states. However, it is challenging to predict the ice loads with high precision. The stochastic characteristics of ice loads increase the complexity of structure design. Permanent plate deflections due to compressive ice loads may happen due to large exposed ice loads (Hänninen 2010). An extreme case is the famous Titanic accident in maritime history back to 1912. Obviously, the cruise ship is not considered to take the iceberg impact loads at that time.

Limiting Mechanisms for Ice Loads

In order to identify the actual ice loads, three limiting mechanisms are defined. They are namely termed as limit stress, limit force, and limit momentum.

(a) Limit stress

The ice fails against the structure and the strength of ice determines the ice loads level. This normally gives highest ice loads. The unconfined strength of ice is commonly used to represent the ice strength.

(b) Limit force

The driving force, such as winds, currents, and the surrounding pack ice, are pushing the ice features against wide structures with thinner pack ice failing behind. The load on the structure is given by the wind and current drag on the ice feature leaning against the structure

plus the pack ice driving pushing on the back of the ice feature.

(c) Limit momentum

This mechanism corresponds to the ice mass with certain velocity collides with a structure and the momentum of ice mass is insufficient to envelop the whole structure. The contact force builds up as the initial momentum changes.

Types of Offshore Structure

The design of offshore structure under ice loads largely depends on the loads level of ice events. Meanwhile, the structure types also have significant impacts to the ice loads. The interaction between structure and ice is a complicated process. The physical understandings are still limited. The characteristics of structural geometry shape shall be considered when evaluating the ice loads. Typical offshore structure types are as follows:

- Floating production, storage, and offloading unit (FPSO)
- Semisubmersible floater
- Gravity-based structure (GBS)
- Jackup rig
- Icebreaker
- Offshore supply vessel (OSV)
- Offshore oil tanker
- Liquefied natural gas carrier (LNG)
- Offshore wind turbine

Based on the main dimensions of the offshore structures, they can be categorized as shown in

Fig. 1. Figure 2 shows some of the main concepts used for offshore structures (not necessarily for ice loads).

Types of Interaction Scenario

The interaction scenarios play a crucial role on deriving ice-related loads. For an optimized structure design, the identification of the interaction scenario is of great importance. The typical interaction scenarios are summarized as follows:

(a) Vertical-sided structure

The ratio between the width of structure and the ice thickness determines the likelihood of possible ice failure modes. The crushing of ice against the vertical wall may cause significant local high pressure, as explained by Jordaan (2001). This type of interaction is normally for fixed structures under relative light ice conditions. Figure 3 shows an illustration of this interaction scenario.

(b) Multi-leg

This type of interaction has decreased exposed contact area, and consequently, it may have better performance under harsh wave loads. It is normally used for environment where ice is not severe. The presence of several legs interacting with ice in close vicinity to each other has mutual influences, see the discussions by Karulin and Karlina (2014). The sheltering effect causes unsymmetrical ice loads to legs, which may increase the yawing

Offshore Structure Design Under Ice Loads, Fig. 1 Main offshore structure under ice condition

Offshore Structure Design Under Ice Loads, Fig. 2 Some typical offshore structural concepts with permission of NOAA (2010)

Offshore Structure Design Under Ice Loads, Fig. 3 An illustration of ice sheet crushing with vertical side structure

moment. Figure 4 shows scenarios for a multi-leg platform operating in ice conditions with different heading angles. The potential jamming effect of broken ice could be another hazard to the multi-leg structures.

(c) Sloping-sided structure

Sloping-sided structures break ice upwards or downwards. The corresponding ice failure mode is bending failure and the bending failure results generally lower ice loads. This type of structure has been widely applied to various offshore structures, such as jackets in Bohai sea of China (Yue and Xiangjun 2000), wind turbines in ice covered waters (Barker et al. 2005), and the confidential bridge in Canada (Aïtcin et al. 2016). The main loads are

from ice-breaking failure and ice clearance (Fig. 5).

p-A Relationship for Ice Crushing

The ice-structure interaction is a complicated process. The understanding of it is still limited. For simplification, ice crushing failure pressure could be determined by the contact area (Sanderson 1988). The pressure and area relationship is widely used for designing structures under ice actions, see Fig. 6 for an example. It is defined as follows:

$$p = C_p \cdot A^{D_p}$$

where p is pressure, C_p and D_p are both constants. Constants C_p and D_p are depending on various factors, such as the confinement effects, indentation geometry, area of loading, aspect ratio etc., see the discussion by Johnston et al. (1998). The understandings to the background of the pressure-area relationship are crucial for selecting the right combinations.

The pressure p can be either global nominal pressure or local contact pressure, and the constants shall be selected accordingly. The improper selection of constants may cause significant discrepancies on predicting the ice loads. The recommended constants for local pressure and area relationship from ISO 19906 are listed in Table 1.

Offshore Structure Design Under Ice Loads, Fig. 4 An illustration of multi-leg interaction with ice sheet under different heading angles

Offshore Structure Design Under Ice Loads, Fig. 5 Typical ice failure on upward and downward cone

Offshore Structure Design Under Ice Loads, Fig. 6 A typical pressure area relationship plot

Local Structure Design Under Ice Crushing

In this section, the main principles of the local structure design are presented. The related regulations, the pressure area relationship and the theory behind the plate design equations are shown.

Related Regulations

The design of local structural scanting shall follow the rules that classification society has given. The main relevant ice regulations are as follows:

- The Finnish-Swedish Ice Class Rules, FSICR (Finish-Swedish 2017)

- The Russian Maritime Register of Shipping ice rules (RMRS 2005)
- The unified Polar Class (PC) rules of the International Association of Classification Societies (IACS 2016)
- The DNV rules for classification of ships, Part 5 Chapter 1 (DNV 2003)

A design patch load (uniform distributed pressure load) shall be established prior to the structure design. Figure 7 shows an example of effective contact area for structure exposed to ice sheet. The detailed procedures on how to derive the effective contact area can be found in related regulations, such as the DNV ice rule (DNV 2003).

Plastic Plate Strip Analogy

The regulations mentioned above are using either elastic or plastic analogy to derive the design

Offshore Structure Design Under Ice Loads, Table 1 Summary of constants for local pressure and area relationship, from ISO 19906 (ISO19906 2010)

Interaction scenario	Pressure type	C_p	D_p
First-year level ice	Local	2.35	-0.50
Thick, massive ice	Local	7.40	-0.70

equations, together with correction factors accounting various design scenarios.

Assuming a three-hinge mechanism for a deformed plate with unit length under uniform pressure p , the plate width is b , as shown in Fig. 8. The critical loads q could be obtained by equaling external virtual work with internal virtual work (Jørgen 2007).

External work:

$$W_e = \int_0^s p \cdot w(x) dx = pb \cdot \frac{dw}{2} \quad (1)$$

Internal virtual work:

$$W_i = M_p(d\theta + 2d\theta + d\theta) = 4M_p d\theta \quad (2)$$

And we have:

$$dw = \frac{b}{2} d\theta \quad (3)$$

So:

$$p = \frac{16M_p}{b^2} \quad (4)$$

Offshore Structure Design Under Ice Loads, Fig. 7 An example of effective contact area

Offshore Structure Design Under Ice Loads, Fig. 8 Plate strip analogy (plastic analysis)

Offshore Structure Design Under Ice Loads, Fig. 9 Roof-shaped yield line pattern for plate under uniform pressure load

The unit plastic bending moment is defined as follows:

$$M_p = \sigma_y W_p = \sigma_y \frac{t^2}{4} \quad (5)$$

where σ_y is the yield stress.

Combining Eqs. (1)–(5), the relationship between plate thickness and the critical external loads can be established.

$$t = \frac{b}{2} \sqrt{\frac{p}{\sigma_y}} \quad (6)$$

Equation (6) is obtained from plastic analysis for a plate with unit width under uniform distributed loads. For the plate exposed to ice load patches, a two-dimensional plastic analysis may be performed. Figure 9 shows a typical yield line pattern for a plate under uniform pressure load (patch load). The plastic analysis can be used to derive the design equations for plate thickness (Chen and Han 1988). Sobotka presents solutions for plate under loads other than uniform pressure (Sobotka 1989).

Based on the failure pattern as shown in Fig. 9, the plastic load-carrying capacity in bending for fully clamped plates is expressed by the following equation, see (Wood 1961):

$$p = \frac{12\sigma_y t^2}{l^2 \alpha^2} \quad (7)$$

where α is called the aspect ratio and defined as $\alpha = \frac{b}{l} \left(\sqrt{3 + \frac{b^2}{l^2}} - \frac{b}{l} \right)$. l is the length of load patch, and b is the patch load height.

Equation (7) can be rewritten as:

$$t = \frac{b}{2} \sqrt{\frac{p}{\sigma_y}} \left(\sqrt{1 + \frac{1}{3} \frac{b^2}{l^2}} - \frac{1}{\sqrt{3}} \frac{b}{l} \right) \quad (8)$$

In IACS (2016), the plate thickness design equation is as follows after let $l = s$ (without the safety factors).

$$t = \frac{b}{2} \sqrt{\frac{p}{\sigma_y}} \frac{1}{1 + 0.5(b/s)} \quad (9)$$

Offshore Vessel

Zhuang Kang and Wen-Chi Ni
College of Shipbuilding and Ocean Engineering,
Harbin Engineering University, Harbin,
Heilongjiang, China

Synonyms

[Offshore engineering vessel](#); [Offshore ship](#)

Definition

Offshore vessels are ships that specifically serve operational purposes such as oil exploration and construction work at the high seas.

Scientific Fundaments

Composition and Basic Type

As mentioned, above, the denotation of offshore vessels is a collective reference and as such includes a wide array of vessels employed in the high sea sector. They can be mainly classified into the following main groups:

- Oil exploration and drilling vessels
- Offshore support vessels
- Offshore production vessels
- Construction/special purpose vessels

Each of this category comprise of a variety of vessels.

Oil Exploration and Drilling Vessels

Oil exploration vessels, as the name suggests, help in exploration and drilling of oil at high seas. The main types of exploration vessels are:

Drilling Vessels Drill ships are special purpose ships which are used for drilling on the ocean beds at deep seas. Drill ships are inherently ships designed to provide optimum viability while on water, thus making it easy for the conglomerates to engage their services for better qualitative results in the overall scheme of drilling viability and functionality (Gouldin et al. 2017).

Drilling vessels can also be used as an analytical vessel to carry out sub-water researching operations in the high seas. The drilling equipment aboard these vessels can penetrate to really greater depths (anywhere over 600 m to over 3000 m) and can be relocated in the high seas as the requirement necessitates. Likewise, the drilling equipment aboard the oil drilling vessels can also be employed to shoal areas to carry out the necessarily required maritime operations.

In order to help them stabilize in the water, these vessels utilize equipment like GP systems

Offshore Vessel, Fig. 1 Drill ship. (<http://www.ussfreedom.org/home>)

and exceedingly strong support cables and ground tackles to keep them firmly positioned in the drilling area. The construction of a drill ship involves a crane-like framework to hoist and lower the required drilling apparatuses from and into the water from a hatchway specifically constructed to pass through the vessel, into the water's depths to aid the process. This feature of the offshore drilling ships makes them highly economical and conducive to the high seas drilling, in addition to the aforementioned aspects (Fig. 1).

Semisubmersible Vessels Semisubmersible vessel is majorly used in marine operations carried out in the high seas like oil drilling and production platforms for oil. In addition, semisubmersible ships are also used as heavy-duty cranes.

The semisubmersible vessel was developed because of the need for vessels that could stay afloat and carry out their required functions in the high seas amidst the constant movement of the waves.

The concept of a semisubmersible vessel emerged toward the early twenty-first century. According to many sources, Shell Company's Bruce Collipp is regarded as the pioneer and creator of these big ships. But it is also said at the same time that the idea behind the semisubmersibles was that of Edward Robert Armstrong, who utilized the

theory of landing planes in sea platforms supported by ballast tanks in a columnar form.

At first, semisubmersible rigs were designed only to be used in shallow waters. Such rigs could be used in water levels up to 30 m. But later on as the need was felt for rigs which could be operated in more depths, the invention of the marine equipment developed and widened.

The first recognized and acknowledged semisubmersible vessel was the one launched by the Blue Water Drilling Company in the year 1961. The name of the rig was the Blue Water Rig No. 1. Another semisubmersible rig was launched in the year 1963 and by 1972; the offshore marine operations had about 30 semisubmersible rigs operating (Minton 1967) (Fig. 2).

Offshore Barge A barge is a flat-bottomed boat, especially built for river and canal transport of heavy goods. Barges these days are actually used to transport low-value bulk items as the cost of hauling goods by barges are cheaper.

A typical barge measures 195 by 35 ft (59.4×10.6 m) and can carry up to 1500 t of cargo. Other than barges, the different types of shipping vessels that are used are container ships, bulk carriers, and tankers. All in all they serve the same purpose of carrying cargo, goods,

Offshore Vessel, Fig. 2 Semisubmersible vessels. (<http://www.Fallschirmjäger/wikipedia.org>)

materials, and sometimes even vehicles or people from one port to another.

A classic barge is very similar to a very large raft. In many cases, a barge is unpowered and has to be moved with the assistance of a tugboat. In this situation, the captain and first mate are aboard the tugboat, not the barge, as the tugboat is providing the power and steering for the barge.

On self-powered barges, the crew includes a captain and first mate to steer the boat and manage the crew, and a small superstructure is usually mounted on the rear of the barge (Fig. 3).

Offshore Support Vessels

Certain offshore vessels provide the necessary manpower and technical reinforcement required so that the operational processes in the high seas continue smoothly and without any undesired interruptions. Such vessels are called as offshore support vessels.

Offshore supply vessels transport the required structural components to the designated high sea sector along with providing assistance to supply freight as well. The constructional aspect of these

vessels can be purpose-built to suit the operational demands. Some of the main types of offshore support vessels are:

Anchor Handling Tug Vessel (AHTV) AHTS vessels are a type of supply vessels that supply tugs and anchors to not just oil rigs but also to cargo-carrying barges. Technically, an AHTS is a very huge naval vessel, mainly because of the equipment that it carries – tugs and anchors along with the winches. In order to transport such a heavy bulk in a manner that they are lost while the AHTS is moving, it is but natural that the design and construction of such ships has to be accommodating to fit such equipment easily.

In addition to towing and tugging oil rigs, another major feature of such anchor handling vessels is that they also act as rescue vessels for other ships in times of some emergency. If a ship or a boat requires immediate anchor handling or towing or tugging, and if an anchor handling tug is in the oceanic vicinity, then they are a great source of help to such stranded vessels (Fig. 4).

Offshore Vessel, Fig. 3 Offshore barge. (<http://www.JeremyA/wikipedia.org>)

O

Offshore Vessel, Fig. 4 Anchor handling tug vessel (AHTV). (<http://www.BoH/wikipedia.org>)

Seismic Vessel For the purpose of seismic survey, seismic waves are the main components that are analyzed. The process involves a seismic detector that shoots such seismic waves to a selected underwater point. The time taken for the waves to refract back to their origin point determines whether that particular subsea area is feasible for the oil drilling purpose.

A survey vessel is the one that helps monitor such seismic waves. It is the primary requirement for any shipping concern engaged in or planning to engage in the process of oil and gas excavation from the oceanic reservoirs. A seismic vessel is fitted with all technological gadgets like GPS, computers, nautical charts, and any other equipment that would enhance the process of seismic survey.

Such vessels are built very carefully and only in selected locations across the world (Eisner et al. 2011). This is because the entire ship-building process for seismic vessel involves fitting all the necessary gadgets (mentioned above) without missing even a single one. Seismic vessels are more in demand in today's time considering the

amount of subsea drilling that is being carried out. They are also known as research vessels because in a completely different way, they do help research the oceans and seas (Fig. 5).

Platform Supply Vessels (PSVs) Platform supply vessels or PSVs is a type of offshore vessel which is mainly used for transiting essential equipment and additional manpower to reinforce the high seas' operations.

A platform support vessel is, at its broadest and most literal of implications, a much-needed support ship. Synonymously referred to as offshore supply vessels (OSVs), platform supply vessels help to sustain the demands of the constructional and maintenance projects, thus fulfilling a vital necessity in the nature of operations at the high seas.

The singularity of OSV ships stems from numerous factors, even aside from its unique role in the high seas constructional sector. Under a broader ambit, supply vessels help to lug not just heavy structural equipment but also smaller yet essential structural components like paving

Offshore Vessel, Fig. 5 Seismic vessel. (<http://www.SludgeG/Wikipedia>)

material (cement and concrete) and chemical compounds that help in efficient sub-water boring operations. In addition to these, food and provisions to the crew and personnel working in the high seas is also transported by way of these supply ships.

Personnel discharged from active line of operations in the high seas are also transported back to the nearest harbor facilities by way of these incoming supply vessels. Since OSV ships transit personnel, these vessels come furnished with cookhouses and other necessary facilities to facilitate an easy transiting for the personnel. In terms of their technical proportion, OSVs can measure anywhere between 65 ft and over 300 m. This aspect about platform supply vessels adds to their operational singularity.

A platform support vessel can be custom-built to suit the operational needs of its operators. Consequentially, not all PSVs are employed to transit drilling rig platforms or sub-water cables to help in the oil excavation operations (Dong et al. 2017). They are also utilized for the purposes of curbing the extent of oil spillage in the high seas

and also as handy vessels with fire-controlling instrumentation.

Presently, the need for PSVs has started to be felt more and more as compared to the past few years. This is on account of the constant rise in the number of operations in the high seas, which has in turn resulted in the advancement in the construction of the supply vessels. This demand fuelled the need for more of these vessels and coupled with the benefits of modern technologies can very well be considered as a positive thrust in a very viable and highly necessitated medium of operation (Fig. 6).

Offshore Production Vessels

Offshore production vessels refer to those vessels that help in the production processes in the drilling units in the high seas. FPSOs (floating production storage and offloading) can be enumerated as an example of these types of offshore ships. The main type of these vessels is:

Floating Production Storage and Offloading (FPSO)

The FPSO (floating production storage

Offshore Vessel, Fig. 6 Platform supply vessels (PSVs). (<https://www.marineinsight.com>)

and offloading) system is used extensively by oil companies for the purpose of storing oil from the oil rigs in the middle of the ocean and in the high seas. It is one of the best devised systems to have developed in the oil exploration industry in the marine areas.

The FPSO, as its name suggests, is a floating contraption that allows oil rigs the freedom not just to store oil but also to produce or refine it before finally offloading it to the desired industrial sectors, either by way of cargo containers or with the help of pipelines built underwater.

The use of this system ensures that shipping companies do not have to invest even more money by ferrying the raw and crude oil to an onshore refinery before transferring it to the required industrial areas. In simple terms, the FPSO saves time and money effectively (Huser and Rasmussen 2001) (Fig. 7).

Offshore Construction Vessel

Ships that primarily aid in the construction of various high seas structures are known as offshore construction vessels.

Other offshore vessels' of these type also include those that provide anchorage and tugging assistance and those kinds of ships that help in the positioning of deep sub-water cable and piping lines. Main types are:

Diving Support Vessel A diving support vessel, as the name suggests, is a vessel that is used for the objective of diving into oceans. Divers, who dive into the middle of the seas as a part of professional diving process, need proper diving support. This necessary support is provided by such a dive support vessel.

The concept of a diving support vessel came into existence four to five decades ago. From that

Offshore Vessel, Fig. 7 Floating production storage and offloading (FPSO). (<https://www.maersk.com>)

time onward, these ships have been extremely important to the field of commercial diving which forms a vital part of professional diving.

It has to be noted that professional diving means diving for the prospect of construction, repairing, and maintenance of oil rigs and other important offshore naval constructions. Such dive support ships are mainly used in the North Sea and the Gulf of Mexico since these are the areas from where crude oil is majorly excavated from subsea sources.

Such support vessels are flat-based or flat-bottomed because it makes the diving part easy for the divers. Additionally it has to be noted that such ships are equipped with the dynamic positioning system in order to help the vessel used for diving support stay steady on the water. In the absence of the dynamic positioning system, what could happen is that the ship could move away from the intended diving spot which would cause complications to the diver.

Another important feature in vessels that enable diving support is the saturation diving system. The saturation diving system enforces the presence of combination of certain important gases like helium and oxygen for the diver.

Without proper saturation diving system, the diver has to go very deep into the oceanic water, which could cause complications like lack of air leading to suffocation (Fig. 8).

Crane Vessel As the name suggests, a crane ship is that kind of seagoing vessel which has a crane attached to it. A crane vessel is of great significance when it comes to the aspect of constructing structures in the high seas. It is only because of such vessels that many important constructions are carried out in trickier parts of the seas and oceans.

The role and scope of a crane ship is similar to the cranes that are used in day-to-day construction and hauling business activities. The only difference is the fact that the former variation of crane is used in the seas while the latter on firm ground.

The designing of the crane vessel has changed in the 800 years of its origin. The first crane ship was created in the fourteenth century, and since then the technology has helped generations and generations of people. In today's times, along with the basic ship that carries a single crane attached to it, there are also concepts like "semisubmersible vessels" and the "sheerlegs."

Offshore Vessel, Fig. 8 Diving support vessel. (<https://www.wikimedia.org>)

All such crane vessels are capable of lifting heavy tonnage, but different varieties offer different features and USP to their clients. The main difference can be elaborated as follows:

- **Common crane vessels:** These types of naval cranes are more commonly known around. They were the ones that were first introduced in the fourteenth century, as mentioned above. These cranes can be used to haul and lift around 2500 t. Additionally, another major feature is that it is movable, which means, the crane can be moved to the place where the item to be lifted is located, thus offering lots of flexibility.
- **Semisubmersible:** These types of cranes offer a lot of stability to the equipment that is being carried. As the name goes, semisubmersible cranes submerge partially into the water to give the weight placed on top of them the balance required. This balance provided ensures that the item carried does not topple into the water and thereby cause serious problems not just to the business concerned but also to the marine ecosystem. The weight carrying capacity of such semisubmersible cranes varies

from one naval vessel to another. However, the heaviest limit that such semisubmersibles can carry extends to around 14,000 t.

- **Sheerlegs:** These types of cranes are immovable. In other words, the weight that has to be loaded on them has to be brought to them so that they can be hauled. The weight carrying capacity of such cranes varies from around 50 t to around 4000 t.

A crane vessel has enabled to solve the trickiest aspect of construction. Crossing the ocean and helping widespread places to come even closer have become so much easier. Also, in today's times, with the help of a crane ship, important oil rigs are constructed so as to enable the world to get precious oil from oceanic sources (Fig. 9).

Pipe Laying Vessel A pipe laying ship is a maritime vessel used in the construction of subsea infrastructure. It serves to connect oil production platforms with refineries on shore. To accomplish this goal, a typical pipe laying vessel carries a heavy lift crane, used to install pumps and valves, and equipment to lay pipe between subsea structures.

Offshore Vessel, Fig. 9 Crane vessel. (<https://www.MarkFromSavannah/wikipedia.com>)

Lay methods consist of J-lay and S-lay and can be reel-lay or welded length by length. Pipe laying ships make use of dynamic positioning systems or anchor spreads to maintain the correct position and speed while laying pipe.

Recent advances have been made, with pipe being laid in water depths of more than 2500 m.

The term “pipe laying vessel” or “pipe layer” refers to all vessels capable of laying pipe on the ocean floor. It can also refer to “dual activity” ships. These vessels are capable of laying pipe on the ocean floor in addition to their primary job. Examples of dual activity pipe layers include barges, modified bulk carriers, modified drill ships, and semi-immiscible laying vessels, among others (King 2008) (Fig. 10).

Development History

The history of offshore vessel originates from ocean vessels. In the seventeenth–eighteenth century, the great value of trade from India and the East Indies prompts the various East India companies – and particularly those of England and Holland – to invest in magnificent ocean-going

merchant ships. These ships needed to have capacity for storing large amounts of cargo; they need to be strong and well-armed to fight off pirates or even the ships of rival companies; and they need to be comfortable for their captains and for important passengers, busy making fortunes in the east.

These were the most beautiful ships of that time period. The largest classes, outdoing even the biggest warships, were 1200 t in weight. The largest ships of this kind were 50 m long and 12 m wide. With a ratio of 4:1 between length and width, these ships could not achieve a big speed. Speed was not a crucial factor for the East India companies, since they enjoyed the monopoly anyways. The ships used trade winds as assistance in the journey and made just one journey in and out from east per year. With the nineteenth century bringing competition, speed of merchant ships became a factor and the age of clippers came.

As a result of the growing demand for a more rapid delivery of tea from China, in 1843 the Clipper era begun. Clippers were very fast-sailing ships with three or more masts and a square rig.

Offshore Vessel, Fig. 10 Crane vessel. (<https://www.wikipedia.com>)

The demand for clippers continued during the “Golden Rush” when there was a need for quick ships that were used for the transportation of gold.

The decline in the usage of clippers started with the gradual introduction of steamships. Although clippers could reach much higher maximum speed than steamships, they depended on the wind and thus could not be accounted as punctual. As for steamers, they could keep the schedule and this made them more reliable.

The industrial revolution, new mechanical methods of propulsion, and the ability to construct ships from metal triggered an explosion in ship design. The quest for more efficient ships, the end of long running and wasteful maritime conflicts, and the increased financial capacity of industrial powers created an avalanche of more specialized boats and ships. Specialized ships built for entirely new functions, such as firefighting, rescue, and research, also began to appear (Woodman 2005). With the development of offshore engineering, the offshore vessel has also been born.

Key Applications

Offshore vessels are ships that specifically serve operational purposes such as oil exploration and construction work at the high seas.

There are a variety of offshore vessels, which not only help in exploration and drilling of oil but also for providing necessary supplies to the excavation and construction units located at the high seas. Offshore ships also provide the transiting and relieving of crewing personnel to and from the high seas’ operational arenas, as and when necessitated.

Introduction

Climate change caused by the excessive use of fossil fuels has become one of the hot topics in the last few decades and threatens human

security and societal development. Serious environmental pollution and energy crises cause people and governments to look for sustainable energy resources. Offshore wind energy is regarded as one of the fastest-growing renewable energy resources in the world. Compared with onshore wind energy, the deployment of offshore wind energy offers another promising solution because of the improved wind conditions, unlimited sites, negligible visual impact, and the possibility of installing extra-large wind turbines (Perveen et al. 2014).

Offshore wind energy has significant potential in northern regions with cold climates, such as Northern Asia, North America, and Northern Europe. In these regions, wind turbines may experience icing on the blades or drifting ice during wintertime. A great potential for offshore wind is ready to be tapped in the Baltic Sea, with more than 16 GW of Baltic projects (Recharge News 2016). The Icebreaker project of Lake Erie Energy Development Co. (LEEDCo) would include six wind turbines for a total generating capacity of up to 20.7 MW in Lake Erie, north of Cleveland. According to China's 13th Five-Year Plan for offshore wind energy (NDRC 2017), nearly 900 MW of offshore wind projects will begin construction in the Bohai Bay Rim area by 2020.

Bottom-fixed wind turbines are very suitable for the shallow and intermediate water depths (<60 m). In addition to the aerodynamic and hydrodynamic loads, ice loads are also an important design consideration for offshore wind

turbine (OWTs) in ice-infested waters. The design standards for lighthouses, bridges, and offshore platforms supply sufficient information about structural design against ice loads; however, as a high-rise flexible structure (a large RNA located 100 m above the MSL for 5 MW wind turbine), OWTs possess more sensitive dynamic responses and complex dynamic behaviors than offshore oil and gas platforms. The ice load models based on those standards and guidelines are not always suitable for the design of OWT support structures due to the excessive dynamic effects that are typically present in the OWT structures. Therefore, the challenges related to ice loads on OWTs (Fig. 1) have not yet been investigated in detail.

Icing on the OWT turbine and support structures can increase the gravitational and inertial loads, and icing on the blades will increase the mass and modify their aerodynamic performance, with possible effects on aerodynamic loading and power production (Etemaddar et al. 2014a, b). Drifting ice can induce dynamic loads on the support structures, and dynamic interactions with the breaking drifting ice around the structure can excite the structure's natural frequencies. Ice loads on the OWT support structures in cold-weather regions can add risks and increase the cost of construction and maintenance (Salo and Syri 2014). This challenge calls for a detailed study of the ice-structure interactions for OWTs.

An overview of the environmental conditions, including the ice conditions for the Baltic Sea, Bohai Rim area, and Great Lakes, is given in

Offshore Wind Turbine-Ice Interactions,

Fig. 1 An offshore wind turbine at Finland

section “[Metocean Conditions](#).” The icing on the blade and the ice failure modes of the drifting ice on the OWT support structure are discussed in section “[Ice Issues for Offshore Wind Turbines](#).” To design and certify OWTs for use in cold regions, we have to follow different design standards. Section “[Ice Issues for Offshore Wind Turbines](#)” summarizes the current existing ice load models from various international standards. Section “[Numerical Analysis of Ice Load Effects on OWTs](#)” summarizes the current ice load models from various international standards. This section also discusses the numerical analysis methods of the ice-structure interactions for OWTs. It requires consideration of the wind turbine and support structures as a whole. Experimental analyses that give deeper insight into the physical loads and responses have an important role in concept verification and validation of the numerical models (section “[Experimental Analysis of Ice Load Effects on OWTs](#)”).

Metocean Conditions

Ice Conditions in the Baltic Sea

Local ice conditions are important when designing an offshore structure such as an OWT. A comprehensive overview on the seasonal ice conditions occurring onsite is paramount when trying to determine the loads imposed on the OWT support structures, for example, by moving level ice and ice ridge impacts. To optimize the support structure design for locations in the Baltic Sea, mapping of the possible ice conditions occurring onsite is very important.

In the literature, several studies contain statistical data with regard to the seasonal ice conditions in the Baltic Sea and the maximum level ice thicknesses, ice drift speeds, and ice ridge characteristics specific to the Bay of Bothnia (Tikanmäki et al. 2012). Most work makes use of seasonal ice measurement data and daily ice charts from the Finnish Meteorological Institute (FMI). These very specific data contain measured ice thicknesses (Fig. 2), ice concentration, ice drifts, and ice ridge occurrences.

The thickness of the free level ice in the Bay of Bothnia can reach anywhere between 0.3 m and 0.9 m, according to measurements performed over the last 50 years (Määttänen 1999). While land-fast ice shows limited signs of movement, free ice features can show high ice drift speeds.

Ice Conditions in Bohai Bay

Offshore wind energy is an important component of China’s National Energy Development Strategy. According to the Chinese 13th Five-Year Plan for offshore wind energy (NDRC 2017), 15,000 MW offshore wind farms will be constructed, nearly 900 MW of which will begin construction in the Bohai Bay Rim area by 2020. As the only high-latitude cold sea area, Bohai and the northern sea area of Huanghai have great potential for the development offshore wind energy in China (Fig. 3) (IEA 2012). The huge wind energy potential is accompanied by the threat of sea ice and freezing. There is a large challenge in deploying OWTs in such an area because we have to ensure the safe and sustainable operation of wind turbines under the special threat of cold weather.

According to the “Regulations for offshore ice conditions and applications in the China Sea” (CNOOC 2002), the frozen sea area of China, Bohai, and the northern part of Huanghai are divided into 21 ice zones, as shown in Fig. 4. We can easily identify the design thickness of the level ice, the corresponding crushing strength, the flexural strength, and the ice drifting speed and drifting direction in different ice zones from the aforementioned regulations.

Ice Conditions in the Great Lakes

For the development of offshore wind energy in the Great Lakes, an important technological challenge is the presence of ice. There are exceptionally harsh winters in which the ice covers nearly 100% of the surface of the Great Lakes. The impact of ice on power-generating turbines operating offshore in the harsh winter weather of the Great Lakes is a major challenge. Lakes Superior, Huron, and Erie are often substantially covered with ice and have wind-driven ice floes at

Offshore Wind Turbine-Ice Interactions,

Fig. 2 Distribution of mean ice thickness (Finnish Meteorological Institute)

times. Figure 5 shows the estimated maximum thickness of the level ice in the Great Lakes.

Ice Issues for Offshore Wind Turbines

Icing Mechanism on the Wind Turbine Blades

For an OWT in cold regions, at the water surface level and above, there is the buildup of atmospheric icing on turbine blades and support structures due to water in the air as in-cloud operations, rainfall, and sea sprays. Icing on the OWT turbine and support structures can increase the gravitational and inertial loads, and icing on the blades will increase the blade mass and mass imbalance and change the blade surface roughness, thus modifying their aerodynamic performance, with possible effects on aerodynamic loading and power production (Fig. 6). Additionally, ice buildup on turbine blades can lead to ice throw

or shredding, where fragments of mixed ice and snow fall off the blades. The size, speed, and distance of falling fragments vary and depend on the climate conditions and turbine operation. Icing of rotor blades and other wind turbine components have an effect on the design of turbines, the safety of O&M personnel, and the overall economics of a wind energy project. Anti-icing “paint” and deicing or anti-icing systems were developed for modern wind turbines to prevent the formation of ice and to detect and efficiently remove ice formed on wind turbine blades while letting the turbines operate at full power.

The atmospheric ice accumulation on wind turbine blades and its effect on the aerodynamic performance and structural response were investigated using a numerical method (Etemaddar et al. 2014a). Below the rated wind speed, for a 5 MW NREL wind turbine, a power loss up to 35% is observed, and the rated power is shifted

Offshore Wind Turbine-Ice Interactions, Fig. 5 Great Lakes ice chart based on estimated thickness in inches (National Ice Center 2018)

Offshore Wind Turbine-Ice Interactions, Fig. 6 Icing on the wind turbine blades

from a wind speed of 11 to 19 m/s (Fig. 7). The thrust of the iced rotor below the rated wind speed is less than that of a clean rotor by up to 14%,

whereas above the rated wind speed, it is up to 40% greater than that of clean rotor.

Drifting Ice Failure Modes on the Wind Turbine Support Structures

Offshore, the drifting level ice or an ice ridge on the sea surface can induce additional static and dynamic forces on the turbine support structure. The effects of sea ice occur as mechanical shocks and increased vibrations that may result in additional operational loads.

Due to differences in the ice thickness, the ice drifting speed, and the geometry of the structure, ice failure can be classified (ISO 19906 2010) as a crushing mode, which typically occurs against vertical structures (Fig. 8), and a flexural mode, which typically occurs against inclined structures. Depending on the ice speed, the crushing mode

Offshore Wind Turbine-Ice Interactions,

Fig. 7 Mean values of aerodynamic thrust before and after icing

Offshore Wind Turbine-Ice Interactions, Fig. 8 Level ice failure against a vertical structure (Xu et al. 2010)

can be identified (Yue et al. 2009; ISO 19906 2010) as follows:

1. Intermittent ice crushing at low ice velocities, where the ice load time series exhibit a saw-tooth waveform with a specified period that is separated by unloading intervals
2. Frequency lock-in crushing at moderate ice velocities, where the ice load time series exhibit a periodic waveform at a specified fundamental frequency of the support structure

3. Continuous brittle crushing at high ice velocities, where the time series of both the ice loads and the structural response appear to be random

A widely used structural approach is to design the structural member with an incline/decline at the seawater level. A conical structure is commonly used for this purpose (Fig. 9). The cone forces the ice sheet to bend when it collides with the structure, which has two advantages: (1) the failure stress level is much easier to reach for

Offshore Wind Turbine-Ice Interactions, Fig. 9 Level ice failure against a conical structure (Xu et al. 2010)

Offshore Wind Turbine-Ice Interactions, Fig. 10 Level ice bending failure pattern against a conical structure: ① loading, ② unloading, ③ zero-stable force (Xu et al. 2010)

bending compared to compression, and (2) the failure level for ice is much less when bent than when compressed, which is typical for many materials. A typical ice load pattern for the bending failure mode could be identified as the loading, unloading, and zero-stable force phases (Fig. 10).

Numerical Analysis of Ice Load Effects on OWTs

Ice Load Models from International Standards

The ice load models regarding both vertical and conical structures in IEC and ISO standards are summarized in this section.

For the monopile (or vertical cylinder structures), IEC 61400-3, DNV-OS-J101 (DNV 2014), and the GL Guideline utilize the Korzhavin equation to estimate the global static force on vertical structures:

$$F = k_1 k_2 k_3 h D \sigma_c \quad (1)$$

where k_1 is the shape factor for the shape of the support structure on the ice impact side; k_2 is the contact factor for the ice contact against the support structure; k_3 is the factor for the ratio between ice thickness and the support structure diameter; D is the diameter of the support structure at the water line; and σ_c is the crushing strength of the ice.

ISO 19906 proposes a different approach to address the horizontal load due to ice crushing based on full-scale measurements and studies on the influence of the ice thickness and the structure width on the global ice action.

$$F_{cr} = p_G h D = C_R h^n (D/h)^m h D \quad (2)$$

where p_G is the global average ice pressure, C_R is the ice strength coefficient, and n and m are empirical exponents to account for the size effect.

For the conical structures, in IEC 61400-3 (2009), Ralston's formulae, which have also been used as recommended practice in DNV and API standards (API 2007), are adopted to

calculate the static ice loads on conical structures. For downward breaking cones, the static characteristic values for horizontal and vertical forces on the cone are

$$F_H = A_4 \left(A_1 \sigma_f h_i^2 + \frac{1}{9} A_2 \rho_w g h_i D_{wl}^2 + \frac{1}{9} A_3 \rho_w g h_i (D_{wl}^2 - D^2) \right) \quad (3)$$

and

$$F_V = B_1 F_H + \frac{1}{9} B_2 \rho_w g h_i (D_{wl}^2 - D^2) \quad (4)$$

where A_i and B_i are nondimensional coefficients determined from a reference (Ralston 1977), ρ_w is the water density, and D is the cone diameter at the bottom for the downward cone.

For dynamic loading on conical structures, IEC recommends the following vertically shifted sinusoidal model:

$$F_{H,dyn} = F_H \left(\frac{3}{4} + \frac{1}{4} \sin(2\pi f_b t) \right) \quad (5)$$

where F_H is the maximum load derived from the static characteristic value (Eq. 3), $f_b = V_i/(Kh_i)$, V_i is the ice drifting speed, h_i is the ice thickness, and $4 < K < 7$. The value of K that gives the highest load that should be used.

IEC also suggests a sawtooth model for dynamic loading on conical structures as in Fig. 11.

Popko et al. (2012) studied the sea ice loads on offshore support structures by comparing different ice models from different international guidelines and standards. They indicated that the interaction of sea ice, other metocean loads, and OWT should be considered. IEC 61400-3 offers quite good provisions for ice loads. However, some of the proposed models may be considered not state of the art. ISO 19906 gives a comprehensive set of ice loads for the Baltic Sea region. The DNV document lacks a broad description of ice loads but is harmonized with the IEC standard. Basic provisions for ice loads are given in both GL guidelines. Modern standards for the ice load prediction of offshore structures were reviewed by Frederking (2012).

Numerical Analysis of Ice Loads Effects on OWT

The extents of ice cover, ice thickness, and ice strength are highly variable over space and time. The forces exerted on the wind turbine structure are associated with the geometry, motion, and failure strength of ice. Therefore, the ice forces are also highly variable. In contrast to offshore oil and gas platforms in cold regions, not only are offshore wind turbines subject to coupled forcing from ice, winds, waves, and currents, but their structural responses are also highly influenced by turbine dynamics and forces.

For offshore structures used in the oil and gas industry in cold regions, ice loads may be dominant over wind and wave loads (McGovern and

Offshore Wind Turbine-Ice Interactions,

Fig. 11 IEC sawtooth ice load model (IEC 61400-3 2009)

Bai 2014). Many studies have been conducted to predict the ice loads on cylindrical or sloped offshore structures. Bekker et al. (2009) carried out simulations of the ice-structure interactions between the ice cover and the offshore structures. Bekker et al. (2013) estimated the contact interaction of an ice hummock and ice floe to predict the ice load on a cylinder using commercial CFD software. Zvyagin and Sazonov (2014) used a probabilistic model to simulate the stochastic ice loads. Taylor and Richard (2014) developed a probabilistic ice load model based on an empirical method. Spencer et al. (2014) used the quantile regression method to analyze global ice pressure data for a wide range of structures.

For a 5 MW OWT on a monopile with a diameter of 6 m interacting with drifting ice that has a thickness 0.5 m, the ice-structure interaction could generate dynamic forces as high as a maximum of 15 MN under conservative simplifications (Nguyen et al. 2014). Ice loads on the support structures for OWTs in cold regions could add risks and increase the costs of construction and maintenance (Salo and Syri 2014).

Conical structures have been suggested for most offshore structures where ice is present (Xu et al. 2014). The cone reduces the ice load magnitude and ice-induced structural response compared to a cylindrical structure with the same waterline diameter (Barker et al. 2014).

Wind turbine design and analysis rely on the use of aero-hydro-servo-elastic simulation tools to predict the coupled dynamic loads and responses of an OWT; a limited number of studies have considered fully coupled analyses, which simultaneously investigate the effects of both aerodynamic and ice loads on the behavior of offshore wind turbines. The excitation of a complete OWT structure and the vibration of its blades were reported by Hetmanczyk et al. (2011) in a numerical study on the dynamic ice loads on an OWT. Gravesen and Kärnä (2009) focused on the static ice crushing occurring on a vertical structure of an OWT in the South Baltic Sea based on the ISO standard (2010) with necessary corrections for the ice reference strength. The mitigation of ice-induced vibrations in an OWT was studied using a semiactive model (Mróz et al. 2008)

Offshore Wind Turbine-Ice Interactions,

Fig. 12 Monopile wind turbine with ice-breaking cone (Shi et al. 2016)

and a semiactive tuned mass damper (STMD) system (Kärnä and Kolari 2004). Fully coupled simulations are shown to have lower standard deviations than the superposition of responses under wind-only and ice-only loads (Shi et al. 2014, 2016, 2018) (Fig. 12). Figure 13 compares the shear force at mean sea level for a monopile OWT under various load conditions.

Experimental Analysis of Ice Load Effects on OWTs

Serious ice-induced vibrations of offshore structures have been seen to occur in situ. A limited number of studies measured the ice loads and responses in model tests and field observations involving ice-induced vibrations (Jefferies et al. 2011). Määttä et al. (2011) conducted nearly full-scale ice crushing tests in the Aker Arctic test basin. Frequency lock-in crushing may cause severe vibration at certain ice velocities for cylindrical structures (Bjerkås et al. 2014; Xu et al. 2014; Xu and Yue 2014). It is also important to determine the force and frequency of load cycles for fatigue assessment (Hendrikse et al. 2014). This phenomenon is particularly addressed in the ISO (2010) and IEC standards (2009).

Murray et al. (2009) did model tests on scales of 1:30 and 1:50 to predict the ice loads of an ice-resistant spar design. Nord et al. (2015) identified

Offshore Wind Turbine-Ice Interactions, Fig. 13 Comparison of the shear force in the fore-aft direction at MSL under various load conditions (Shi et al. 2016)

the force induced by level ice on a generic bottom-fixed offshore structure using a joint input-state algorithm to describe experimental ice-induced vibrations. Full-scale testing was conducted by Yue et al. (2009) on a cylindrical monopile in Bohai Bay to investigate the dynamic ice forces and structural vibrations; three speed-dependent ice force modes were observed. Following their previous work, Xu and Yue (2014) experimentally investigated the dynamic ice force on a jacket structure with an upward/downward ice-breaking cone in the Bohai Sea.

Barker et al. (2005) and Gravesen et al. (2003, 2005) performed extensive model testing to investigate the ice-induced vibrations in OWTs in Danish waters. Compared to wind loads, increases of 60% in the maximum force and 10% in the bending moment were estimated for large wind turbines in Denmark (Fig. 14).

Conclusions and Final Challenges

The development of offshore wind energy in cold regions is very attractive; however, it is a big

challenge to deploy OWTs in those regions due to the icing on the turbine blades and drifting ice at the mean sea level during the wintertime. Both icing and drifting ice can have a big effect on the power production and dynamic response of the OWT system. The ice load models from international standards are based on offshore oil and gas industry, which is not well suitable for OWT design and analysis. Great effort has been dedicated to develop fully coupled numerical model for OWTs to take into account the ice load effect. Some experimental studies have been carried out in model scale to validate various ice load numerical models. Numerous countries, in particular the United States, China, and Finland, have aspiration to take full advantage of the offshore wind resources in the Great Lakes, Bohai Bay, and Baltic Sea, facing the ice loads challenge for OWTs.

There remain a number of technical challenges; the key requirements are for:

- *Fully coupled numerical models*, able to simulate the wind turbine system and ice induced vibration dynamically

Offshore Wind Turbine-Ice Interactions,

Fig. 14 Typical time series traces of the failure modes observed during testing (Barker et al. 2005)

- More detailed ice-related design load cases from international standards for turbine design and certification
- A comprehensive program of ice tank test for OWT to develop more accurate ice load model specifically for OWT
- More field test data for OWT-ice interaction

Offshore Wind Turbines

Zhen Gao

Norwegian University of Science and Technology, Trondheim, Norway

Definition

An offshore wind turbine is a modern device that is deployed in an offshore environment for generation of electricity from wind.

Function and Components of a Modern Wind Turbine

Wind energy is one of the most important renewable energy resources that are gaining increasing attention and significant development. A wind turbine is used to convert the kinetic energy in wind first to the mechanical energy through rotation of the blades and then to the electricity via a generator. Modern wind turbine, which has been commercialized and industrialized, is typically a three-blade, upwind, pitch-regulated variable speed horizontal axis wind turbine (HAWT), as shown in Fig. 1 (National Renewable Energy Laboratory (NREL) 2011). An offshore wind turbine is a wind turbine at sea with either bottom-fixed or floating support structures.

A wind turbine consists of tower, nacelle, hub, and rotor blades. Inside the nacelle, there is a gearbox which transforms the low rotational speed of the rotor into the high rotational speed at the generator side. For example, the rotor rotates at 12 rpm for the NREL 5 MW wind turbine at the rated wind speed, while the generator runs at 1164 rpm, indicating a gear ratio of 1:97 (Jonkman et al. 2009). For each blade, there is a pitch actuator at the blade root, typically a hydraulic system, which connects to the hub and allows the change of the blade pitch angle for power regulation for wind speed larger than the rated value. In addition, there is a yaw mechanism which allows the rotor plane facing the main wind direction in order to maximize the power absorption. Electricity generated by each turbine are collected at the substation of a wind farm via AC cables and transmitted to the grid through DC cables.

To reduce the gravity-induced dynamic loads in blades during normal operation, wind turbine blades are made of lightweight and high-strength materials, i.e., composite materials (mainly GFRP (glass fiber reinforced polymer) and occasionally more expensive but stiffer CFRP (carbon fiber reinforced polymer)). At the blade root, steel bolts are embedded into the composite materials and are used to connect to the hub. Gearbox and tower are also steel structures, and in some cases, tower is made of concrete.

In 2017, the top ten wind turbine manufacturers are Vestas, SGRE, GE, Goldwind,

Offshore Wind Turbines, Table 1 Dimensions of MW-scale industry wind turbines

Rated power (MW)	Starting year for commercial use	Blade length (m)	Blade weight (ton)	Hub height (m)	Nacelle weight (ton)
1.3	1995	31	6	68	50
2	1999	44	10	78	75
5	2005	61.5	17	90	240
6	2013	77	25	100	280
8	2016	82	35	138	390

Enercon, Nordex, Senvion, United Power, Envision, and Suzlon (WindPowerMonthly 2017). The size of a single wind turbine, in terms of rated power, blade length, and hub height, has increased significantly in recent years because of the development of the offshore wind industry,

resulting into a big reduction in cost of energy. Rated power is the largest power that a wind turbine can generate and is mainly limited by the capacity of generator. Table 1 shows the typical dimensions of the MW-scale industry wind turbines.

Offshore Wind Turbines,
Fig. 2 Vertical axis wind
 turbines (VAWTs) (Cheng
 2016)

Thrust and Power of a Wind Turbine

Other types of wind turbines, such as vertical axis wind turbines (VAWTs) as shown in Fig. 2, have also been proposed and tested but without a great success for industry development. As compared to HAWTs, VAWTs have a less optimal power coefficient, have large variations in aerodynamic loads and power per revolution, and are not feasible for power regulation through blade pitch control. However, VAWTs are wind direction-independent and can be combined with a generator at the platform level, which leads to a low center of gravity and can potentially improve the hydrostatic stability of floating wind turbines.

Wind turbine blade is specially designed with its aerofoils to utilize the aerodynamic lift force acting on blade cross-sections to drive the rotor to rotate and then absorb wind power. A typical aerofoil cross-section is shown in Fig. 3, in which both the lift (which is perpendicular to the direction of the local wind inflow) and the drag forces (which is along the direction of the local wind inflow) are indicated. Both the lift and the drag coefficients depend on the angle of attack of the flow, α , as shown in the figure.

The relative velocity near the blade tip induced by the rotation of the blade, for example, about

90 m/s for a 5 MW wind turbine running at the rated speed, is usually much larger than the normal wind velocity for example, about 12 m/s rated (Jonkman 2009). Therefore, the torque, which leads the rotor to rotate, is generated mainly by the lift forces acting on the cross-sections near the blade tip. The wind turbine thrust, which is the integrated force on the three blades along the wind direction, is also mainly due to the cross-sectional lift forces. Torque multiplied with rotor rotational speed gives the aerodynamic power, which is equal to the generator power for the wind turbine in a steady-state operation assuming zero energy loss. The aerodynamic efficiency, which is defined as the ratio of the aerodynamic power to the power available in wind inflow, is limited by the Betz limit, $16/27 = 59.3\%$ (Hansen 2008). Aerodynamic efficiency of modern wind turbines can reach 45–50%. The mechanical efficiency, which is defined as the ratio of the generator power to the aerodynamic power, is typically very high, 97% for drivetrain with gearbox.

Automatic control plays an important role in power production of wind turbines. The black curve in Fig. 4 presents the power curve of a typical pitch-regulated variable speed wind turbine. Wind turbine is parked, either idling for very low wind speed in Region I or standstill for

Offshore Wind Turbines, Fig. 3 Lift (L) and drag (D) forces on a wind turbine blade aerofoil (Hansen 2008)

Offshore Wind Turbines, Fig. 4 Power curve of a typical wind turbine (NREL 2011)

wind speed larger than the cut-out value. In Region II with wind speed lower than the rated value and higher than the cut-in value, wind turbine is in operation with a maximum power absorption coefficient through variable speed control, while in Region III with wind speed larger than the rated value and lower than the cut-out value, wind turbine operates to achieve constant power output via blade pitch control.

Power output of a wind turbine strongly depends on the speed of inflow wind.

However, wind speed is not constant at any offshore site, and it varies from second to second and from year to year. The capacity factor, which is defined as the ratio of the annual average power to the rated power, is used to characterize the long-term power performance of wind turbines. Because of steady wind conditions offshore, the capacity factor of offshore wind turbines is typically in the range of 40–60%, larger than that of onshore turbines, 30–40%.

Types of Offshore Wind Turbine Support Structures

The main difference between onshore and offshore wind turbines lies on the support structures. In addition to the basic components that we see in an onshore wind turbine, as discussed above, an offshore wind turbine needs a support structure in the water. Different types of support structures have been proposed, depending on the water depth and soil conditions of the offshore site. These include bottom-fixed support structures that are mainly used in relatively shallow or moderate waters (in the order of 0–50 m of water depth), such as monopile, jacket, gravity base, tripod, and floating support structures for deep waters (with water depth larger than 50–100 m), such as spar, semisubmersible, TLP (tension leg platform) (see Fig. 5) (Wiser et al. 2011). Most of these support structure concepts were used for offshore oil and gas platforms in the past. However, the sizes of oil and gas platforms are usually larger than those used for offshore wind turbines.

Monopiles are cylindrical steel structures which are hammered to the sea bed with a depth close to the water depth. A transition piece is normally used before placing the tower and the remaining wind turbine components. It is connected to the monopile upper part with grout so that the verticality of the tower and the wind

turbine can be ensured. Typically, a monopile has a diameter of 6–8 m for water depth of 0–30 m, while the recently developed XL monopile has a diameter of 10 m for water depth of 40–50 m, supporting 6–8 MW wind turbine. Jacket support structures are typically three-leg or four-leg structures with connecting braces, which have a diameter of 1–2 m. Piles or suction buckets are used to fix the jacket structure to the sea bed. Jackets are transparent to wave loads and can provide a stiff foundation to support wind turbines. GBS (gravity base foundation) typically has a large concrete foundation which does not require a piling operation. They can be pre-assembled with the tower and the wind turbine at the shipyard, wet-towed to the offshore site and lowered down by ballasting.

Floating wind turbines are totally different as compared to the bottom-fixed wind turbines. According to Butterfield et al. (2005), they can be categorized as spar, semisubmersible, and TLP wind turbines, with respect to the floater types and the mooring systems to achieve hydrostatic stability, i.e., ballast-, water plane area- or mooring-stabilized. A spar wind turbine is a floating cylindrical steel structure with a diameter of 8–10 m and a draft of 80–100 m for supporting a 5 MW wind turbine. It uses heavy ballast at the lower part of the spar to lower the center of gravity and to provide the restoring moment in pitch. Typically, a spread catenary mooring system is used,

Offshore Wind Turbines, Fig. 5 Bottom-fixed and floating wind turbines (Wiser et al. 2011)

and in some cases, clump weights are used in combination with taut lines. A semisubmersible support structure has three or four columns separated with a distance to create a large area moment and to provide the restoring effect. The columns are typically connected by either braces or pontoons. Both spread and single point mooring can be applied. A TLP wind turbine is a floating structure stabilized by mooring lines, i.e., tethers of steel tubes. The floater can be a deep draft floater similar to a spar or a semisubmersible-type floater. Ship-type floaters have been proposed for floating wind turbines. However, because of large wave loads and wave-induced rotational motions, they are not suitable for floating wind applications.

The power characteristics of different types of bottom-fixed offshore wind turbines are very similar, while those of floating wind turbines might be slightly different, because of the heeling angles that are induced by mean wind turbine thrust force and mean wave loads. Moreover, the features of dynamic responses of offshore wind turbine under simultaneous wind and wave loads might be very different for bottom-fixed and floating concepts. Blades are slender structures made of light materials, and they can deform significantly under the aerodynamic loads. Therefore, aeroelasticity should normally be considered in loads and response analysis of blades. A particular challenge is to design the steel-composite connection

at the blade root, which takes most of the bending moment resulted from the aerodynamic loads along the blade. For bottom-fixed offshore wind turbines, the dynamic responses in blades, tower, and foundation are governed by the quasi-static responses due to both slowly varying wind loads and first-order wave-frequency wave loads as well as the resonant dynamic responses at the first and the second eigenmodes due to wind loads. For floating wind turbines, there are more prominent coupling effects between the wind- and wave-induced loads and responses. In addition to the rigid-body motions of floating wind turbines at both the resonant low frequency and wave frequency, there exist vibrational responses at the first eigenmode that are important for design of tower and blades.

Recent Industry Development

As compared to onshore wind turbines, offshore wind turbines today still represent a very small proportion, about 3%, of the total installed wind capacity. However, in the last 20 years, there is a significant development of offshore wind turbines with an average annual increase of 30% in installed capacity. By the end of 2017, it reaches 18.8 GW worldwide (GWEC 2018), as shown in Fig. 6.

Offshore Wind Turbines,
Fig. 6 Cumulative
offshore wind capacity
2011–2017 (GWEC 2018)

Offshore Wind Turbines, Fig. 7 Global cumulative offshore wind capacity 2017 (GWEC 2018)

Among different countries, UK and Germany are the two countries with the most installed capacity, followed by China, Denmark, and the Netherlands, as shown in Fig. 7.

Typically, offshore wind turbines are developed and commercialized through a farm configuration with 50–100 units. Bottom-fixed wind turbines are the majority of today's offshore wind farms, and in particular, monopile foundations count for more than 85% of the support structures. A general trend in recent years' development is that larger-scale wind turbines are being developed and installed in deeper water and farther away from shore. Up to now, there exist only 11 floating wind turbines of MW scale that are under the sea tests, including the small wind farm of 5 units with Hywind spar wind turbines in Scotland. Although there exists a significant potential for using floating wind turbines, they only counts for a few percentage of the total offshore wind capacity even for 2030.

On-Bottom Stability of Submarine Pipelines

Fu-ping Gao

Institute of Mechanics, Chinese Academy of Sciences, Beijing, China

Introduction

The on-bottom stability (also termed as “geotechnical stability”) of submarine pipelines mainly involves vertical, lateral, and axial pipeline-seabed interactions under ocean waves and/or current and engineering operating conditions.

Vertical Stability of the Pipeline on and in Seabed

Submarine pipelines that are intended to be buried in the seabed should be checked for possible sinking or floatation in order to satisfy the vertical stability on and in the soil. For the pipelines to be laid on the seabed with low shear or cohesive strength, the bearing capacity of the soil needs to be evaluated. If the seabed soil is, or is likely to be, liquefied under pure waves or combined waves and current, the liquefaction depth should be predicted accurately. Seabed liquefaction can affect both the vertical stability, i.e., sinking and floatation, and the lateral stability of submarine pipelines (see Det Norske Veritas and Germanischer Lloyd 2017).

Ultimate Bearing Capacity

In geotechnical engineering, the ultimate bearing capacity is defined as the theoretical maximum pressure which can be supported without failure by the soil immediately below and adjacent to a foundation. Submarine pipelines can be regarded as shallow foundations installed on the seabed. With reference to a strip footing, three distinct modes of failure have been identified, i.e., general shear failure, local shear failure, and punching shear failure. The evaluation for the ultimate bearing capacity can be considered in terms of plasticity theory, e.g., the slip-line stress field theory, the lower and upper bound theorems in limit analysis (Chen and Liu 1990).

The seabed soil can be essentially assumed to behave as a Tresca material under undrained conditions, or as a Mohr-Coulomb material under drained conditions. Taking into account the effects of the geometric curvature of the pipe and the adhesion or friction at the pipe-soil interface, the slip-line field solutions for the undrained and fully drained conditions can be derived, respectively (Gao et al. 2013, 2015). A general slip-line field solution for the ultimate bearing capacity of a pipeline on the soil obeying Mohr-Coulomb yield criterion is expressed as (Gao et al. 2015):

$$\frac{P_u}{D \sin \theta} = cN_c + qN_q + (0.5D\gamma' \sin \theta)N_\gamma \quad (1)$$

where P_u is the collapse load for the soil suffering general shear failure (in kN/m); D is the outer diameter of the pipeline (in m); $\theta = \arccos(1 - 2e/D)$ is the embedment angle (in degree), e/D is the embedment-to-diameter ratio; “ $D \sin \theta$ ” refers to the efficient width of the pipe-soil interface, which is related to the pipe penetration; c is the soil cohesion (in kPa); q is the surcharge pressure (in kPa/m) (note: for $e/D \leq 0.5$, q is set to zero; for $e/D > 0.5$, the pipeline embedment can be treated as $e/D = 0.5$ with an equivalent uniform surcharge pressure $q = (e - 0.5D)\gamma'$, where γ' is the buoyant unit weight of the soil (in kPa/m³)); and N_c , N_q , and N_γ are the bearing capacity factors for the cohesion, for the distributed load, and

for the buoyant weight of soils, respectively. For the clayey seabed under undrained conditions, if neglecting the effects of the pipe geometric curvature ($e/D \rightarrow 0$), the pipe-soil interface adhesion (i.e., the interfacial friction coefficient $\mu = 0$), and the internal friction of the soil (i.e., the angle of internal friction $\varphi = 0$), the slip-line field solution can be degenerated into Prandtl’s solution for conventional strip footings, i.e., $N_c = 2 + \pi$. With increasing pipeline embedment, the value of N_c decreases from $N_c = 2 + \pi$ at $e/D \rightarrow 0$ and finally reaches $N_c = 4.0$ at $e/D = 0.5$. It has been indicated that the geometric curvature effect is unneglectable when evaluating the ultimate bearing capacity of submarine pipelines.

Note that the aforementioned solutions were obtained under the assumption that the seabed soil is described with a perfectly plastic stress-strain relationship. Such approximation is applicable for the soils of low compressibility, which might meanwhile correspond to the general shear mode of failure. However, for a very soft clayey seabed, large settlements of the pipeline may occur under its submerged weight and laying disturbances without general shear failure occurring. In such cases, the limiting criterion for bearing capacity should be the maximum allowable settlement.

Seabed Liquefaction

Seabed liquefaction is the phenomenon that the seabed sediment loses a significant part of or all its shear strength under the action of ocean waves or earthquake. Both residual and oscillatory mechanisms for the wave-induced pore pressure response in the seabed have been identified in flume experiments and field observations. The residual liquefaction of the seabed is due to the pore pressure buildup under undrained or partially drained conditions, which usually takes place in fine sands or silty soils under severe wave loading and always combined with currents in the offshore field.

Besides residual liquefaction, the instantaneous liquefaction (also termed as “momentary liquefaction”) is particularly prone to occurrence in seabed sediments during severe storms, which

is essentially caused by the instantaneous upward seepage within the upper layer of the seabed under wave troughs. In the instantaneously liquefied layer of the seabed, the vertical gradient of excess pore pressure (j_z) should be identical to the buoyant unit weight of the soil (γ'), i.e., the improved criterion for instantaneous liquefaction (Qi and Gao 2018): $j_z \cong \gamma'$. Based on the analytical solution to Biot's consolidation equations for porous seabed response to waves (Yamamoto et al. 1978) and the above criterion for instantaneous liquefaction, the maximum depth of instantaneously liquefied layer (z_L) under wave troughs can be derived (Qi and Gao 2018):

$$z_L = \frac{p_0}{\gamma'} - \frac{1}{\text{Re} [\lambda(1 - \alpha) + \lambda'\alpha]} \quad (2)$$

where p_0 is the amplitude of wave-induced excess pressure at the seabed surface; the operator "Re{" means to take the real part of the complex variable in the brackets; $\lambda(=2\pi/L)$ is the wave number; L is the wavelength; α and λ' are the complex numbers related to the properties of the seabed and waves (see Yamamoto et al. 1978).

If the pipeline is to be buried in a liquefiable seabed, the designed burial depth should be larger than the maximum depth of instantaneously liquefied layer (see Eq. 2). To keep the buried pipeline vertically stable, the residual liquefaction of the soil around the pipeline needs to be further evaluated. Moreover, under the condition that waves and current coexisting in the field, the seabed liquefaction and the on-bottom stability of the pipeline should be accurately predicted.

Lateral Stability

In submarine geological and hydrodynamic environments, the multi-mechanics processes can emerge in the proximity of as-laid pipelines, including shear flow above the seabed, sediment transport along the seabed surface, the excessive pore pressure in the soil, etc. They are generally coupled with each other and have significant influence on the lateral stability of submarine pipelines (Gao 2017).

The triggering mechanisms for the pipeline lateral instability involve not only pipe-soil interactions (Wagner et al. 1989; Zhang et al. 2002; Youssef et al. 2013; Gao et al. 2016) but also flow-pipe-soil coupling process (Gao 2017). Experimental observations (see Fig. 1) with an oscillatory flow tunnel showed that there always exist three characteristic stages during the lateral instability of a pipe shallowly embedded in sands under a storm-like wave loading, i.e., (a) local scour of sands around the pipe, (b) periodic rocking of the pipe with small amplitudes, and (c) pipe breakout from original location (see Gao 2017). In the process of the pipe losing lateral instability, local scour always emerges as an indicator for the flow-pipe-soil coupling effect, which was observed taking place at the rear and front of the pipe. The pipe periodic rocking due to the vortex shedding may increase its penetration into the seabed and further affect the lateral stability. The occurrence of pipeline instability is characterized by a distinct lateral displacement (e.g., $d_p/D > 0.5$, where d_p is the pipe lateral displacement, see Fig. 1).

The criteria for pipeline lateral instability are crucial to the on-bottom stability design. Based on similarity analyses for physical modeling experiments, it was found that the controlling non-dimensional parameter of hydrodynamics for pipeline lateral instability is the Froude number ($Fr = U_m/\sqrt{gD}$) and another parameter is the non-dimensional submerged weight of pipelines ($G = W_s/\gamma'D^2$, where U_m is the maximum velocity of wave-induced water particle movement and g is the gravitational acceleration. Both the scaling of the Froude number and that of the Keulegan-Carpenter number ($KC = U_mT/D$, where T is the wave period) can be concurrently satisfied in the physical modeling with wave flumes. KC number essentially controls the generation and development of vortex around the pipeline under oscillatory flow in waves. A unified formulation of criteria for pipeline lateral instability in waves and currents can be expressed as (Gao et al. 2003)

$$Fr_{cr} = a + b \frac{W_s}{\gamma'D^2} \quad (3)$$

On-Bottom Stability of Submarine Pipelines, Fig. 1 Characteristic stages during the pipeline losing lateral stability under a storm-like wave loading (Adapted from Gao 2017)

where Fr_{cr} is the critical values of Froude number for pipeline lateral instability. In Eq. (3), the two parameters a and b are relative to the hydrodynamic loads (periodic waves or steady current), the end constraint conditions (anti-rolling or freely laid) of a shallowly embedded pipe, and the soil properties of the seabed. On the basis of the results of a series of experiments, the values of these two parameters were determined as $(a, b) = (0.07, 0.62)$ for the anti-rolling pipes in waves and $(a, b) = (0.042, 0.38)$ for the freely laid pipes in waves ($5 < KC < 20$). But for the freely laid pipes in a steady current ($KC \rightarrow \infty$), $(a, b) = (0.102, 0.423)$, indicating the pipes are more stable in currents than in waves due to the inertia effect of wave movements. It should be noted that the above recommended values for the two parameters a and b were based on the results of model tests on a uniform medium sand-bed. The particle size is closely related to sediment transport and further affects the lateral stability of the pipeline.

The instability criteria in the unified formulation by Eq. (3) provided alternative expressions to the pipe-soil interaction model by Wagner et al. (1989) for the on-bottom stability of a shallowly embedded pipeline, as addressed by Fredsøe (2016).

Besides the aforementioned lateral instability, submarine pipelines could also be under the threat

from tunnel erosion due to the seepage failure of its underneath soil, especially under the action of shear flow near the seabed, which may further bring the spanned pipeline undergo vibrations, i.e., vortex-induced vibrations (Gao 2017). It has been revealed that the two typical scenarios, i.e., the lateral instability of the pipe and the tunnel erosion of the soil, are always competitive between each other in the submarine geological and hydrodynamic environments (Shi and Gao 2018).

Axial Pipe-Soil Interactions

As offshore developments extend into deep waters, the relatively high pressure and high temperature (HPHT) becomes a dominant factor for the pipeline safety. The HPHT pipeline would undergo expansion and contraction during start-up and shutdown cycles in the operating life, which may induce pipeline walking on the seabed. It should be noted that the pipeline walking is not a limit state; nevertheless, the excessive compressive force can lead to severe global buckling of the pipeline and even the failure of associated infrastructures (Randolph and Gourvenec 2011).

The ultimate axial soil resistance (F_{Ru}) to a conventional strip footing with flat bottom is generally linked with the normal pipe-soil contact

force (F_N) and the interface friction coefficient (μ), i.e., $F_{Ru} = \mu F_N$. But for submarine pipelines, the assessment of ultimate axial soil resistance becomes much more difficult than that for conventional strip footings. Due to the effect of pipeline curvature, the integrated normal pipe-soil contact force (F_N) would exceed the submerged pipeline weight (W_S), i.e., $F_N = \zeta W_S$, by incorporating a wedging factor (ζ):

$$\zeta = \frac{2 \sin \theta_0}{\theta_0 + \sin \theta_0 \cos \theta_0} \quad (4a)$$

for clayey soils (White and Randolph 2007) and

$$\zeta = \frac{1 - (2\theta_0/\pi)^2}{\cos \theta_0} \quad (4b)$$

for sandy soils (Shi et al. 2019), respectively. In Eqs. (4a) and (4b), θ_0 is the semi-angle subtended at the pipe-soil contact chord.

The axial soil resistance expressed with an equivalent friction coefficient could span an order of magnitude, which is related to many influential factors, including the soil types, drainage condition, and the pipe roughness. A theoretical framework was developed within a critical-state context using effective stresses, applicable to any degree of drainage in the soil, quantifying the magnitude and duration of excess pore pressures generated near the pipe-soil interface (Randolph et al. 2012). It has been recognized that the axial soil resistance is crucial for assessing the effective axial force along the pipeline and the corresponding global buckling predictions.

Cavitation test; Open water experiment; Open-water test

Definition

The open water test is a propeller model running alone in uniform current, which can be carried out in the model laboratory, circulating water channel and cavitation tunnel. The open water test can estimate the propeller operating performance as a simple and reliable way to determine and analyze propeller performance. Torque, thrust, speed, and rotate speed are tested at the same time and a series of characteristic curves are obtained through the propeller model open water test and provided information for the later research. Propeller Series Diagram is compiled based on the open water characteristic curves obtained from a large number of experimental results in the tank, used for propeller design, calculation and other applications. The B type propeller in the model pool of the Dutch ship is the most famous propeller pattern, while the AU type propeller pattern in Japan is the most frequently used as well.

The propeller model test is a convenient method to examine and analyze the performance of propellers, which is significant in studying the

hydrodynamic performance of propeller. It can provide sufficient information for propeller designs and a reliable basis for the development of propeller theory.

There are several purposes of open water test:

1. With a set of experiments, drawing the results into a particular graph for design.
2. According to the results, analyzing the influence of various geometry elements on the propeller.
3. As an indispensable means of checking and verifying theoretical methods.
4. Comparing the advantages and disadvantages of various design schemes and choosing the prime by cooperating with self-propelled experiment.

Scientific Fundamentals

Historical Development

As the most widely used Marine propeller, the performance of the propeller research mainly concentrated in the pool experiments. As far as the propeller itself is concerned, its operating efficiency in a uniform flow is the most basic important performance index, and the open water test is the most commonly used effective tool of studying this kind of performance. To date, the open water test of single propeller has been studied for hundreds of years, while the open water test of combined propeller such as ducted propeller and counter-rotating propeller has been conducted for decades.

Basic Classification

Model tests carried out in the laboratory.

The open water test can be carried out on the propeller, rudder, etc., by the model test in the experimental pool, and the measured data can be sorted out and analyzed to obtain a series of characteristic curves for subsequent calculation.

Open water tests of propellers are used in conjunction with tests behind models to determine the wake and relative torque efficiency (Tupper 2013). Also, methodical propeller testing is

carried out in a towing tank. The propeller is powered from the carriage through a streamlined housing. It is pushed along the tank with the propeller ahead of the housing so that the propeller is effectively in undisturbed water (Tupper 2013). Records of thrust and torque are taken for a range of carriage speeds and propeller revolutions (advance coefficient) (Tupper 2013). Such tests eliminate cavitation and provide data on propeller in uniform flow. This methodical series data can be used by the designer, making allowance for the actual flow conditions. (Tupper 2013). There have been many methodical series. Those by Froude, Taylor, Gawn, Troost, and van Lammeren are worthy of mention. The reader should refer to published data, if it is wished to make use of these series. A typical plot for a four-bladed propeller from Troost's series is presented in Fig. 1 (Tupper 2013).

Numerical Calculation

First of all, the numerical algorithm of the open water performance of the propeller with regard to the numerical calculation of the open water performance has been developed very early. As early as the early twentieth century, Lanchester and others began to study the propeller theory and further study was completed by Prandtl. Then Goldstein put forward the Goldstein theory and the Goldstein factor in 1929. Theoretically, the flow field can be simulated by solving the N-S equation and related equations, so as to solve the problems of propeller correlation performance. However, the process of solving the N-S equation becomes very complicated due to some assumptions made in the process of establishing the N-S equation, as well as the complexity of the practical problems and boundary conditions, and the huge amount of calculation seriously restricts the

Open Water Test, Fig. 1 A typical plot for a four-bladed propeller from Troost's series

development of this method. After nearly a hundred years of research by related scholars, three classical theoretical methods, namely lift line theory, lift surface theory and surface element method, were formed on the basis of potential flow theory, which greatly promoted the study of propeller hydrodynamic performance.

At present, many scholars consider the performance of propeller by building solid model. Solid modeling means that hull, propeller, and other appendages no longer adopt the equivalent alternative method, but build solid model and calculation domain together, in which each model is either static or moving. In the solid modeling calculation, the paddle processing can be divided into three types: multiple reference frame (MRF) method, mixed surface method, and slip surface method.

MRF method is to divide the whole computational region into multiple subdomains. Individual subdomains have their own forms of motion such as stationary, moving and rotating, and these subdomains can be considered to maintain the steady state approximation at different moving or rotating speeds. By solving the governing equations of each subdomain and exchanging the flow information of each subdomain on the general interface, the flow information of the whole flow field computing domain can be obtained. If the meshes on both sides of the subdomain interface are not completely consistent, the flow information on the interface is transmitted by interpolation. MRF method is suitable for many conditions of steady flow, especially when the flow area is almost uniform at the boundary.

The hybrid plane method also divides the whole computing domain into several independent subdomains. Instead of each of these little domains being seen as a steady state approximation at different velocities of motion or rotation, each little domain is a steady state. It is considered as a steady flow in the subdomain, and a mixed surface similar to boundary conditions is constructed on the interface between the subdomains to transfer the flow information of both subdomains. The mixed plane method can solve the unstable problems caused by the circumferential changes among the subdomains, such as the

steady-state and flow separation, and then obtain a stable solution.

When using the slip surface method for calculation, there are multiple subdomains in the entire flow region, and there are relative motions between these subdomains, as well as interfaces between every two of them. During the calculation process, the part of the interface that is connected with the adjacent subdomain is called the internal region, and the other part that is not connected with the adjacent subdomain is called the plane region as solving the plane problem. And the part in dealing with periodic or aperiodic problems is called the periodic region. In addition, while using the sliding grid technology, the grids on the interface are irregular, namely the grids on both sides of the interface are not completely consistent. In other words, the relative movement between two adjacent subdomains should be recalculated to obtain the boundary position of the internal region in the specific calculation. This kind of calculation is complex, requiring a high performance of the computer. Compared with the MRF method and the mixed surface method, the slip surface method has a certain advantage in solving periodic or aperiodic problems.

At present, sliding grid technology is often used to transfer flow field information. In the meantime, the calculation methods include lift line method based on potential flow theory, lift surface method, surface element method, and viscous flow method based on RANS equation. Four methods are described below.

The lift line method proposed by Goldstein in 1929 is applied to propeller performance prediction. In this method, all the attached vortices of the propeller are concentrated on a spreading line from the blade root to blade tip, which is called the lift line of the propeller. The strength of the lift line changes along the spanwise direction, and the tail vortex surface is formed downstream of the propeller by the change of the strength of the attached vortex. With the circulation distribution, it is possible to obtain the lift force of each micro-segment vortex element and then obtain the hydrodynamic performance parameters of the propeller accordingly.

The lift surface method is based on the thin airfoil characteristics of Marine propellers. On the one hand, the thickness part only contributes to the pressure distribution of the blade, which is expressed by the source-sink distribution on the chord surface of the wing. On the other hand, the bending part is the origin of lift, which is represented by the vortex distributed on the chord surface of the wing. The boundary conditions are satisfied on the wing chord. Because the boundary conditions of lift surface method are stricter than the lift line method, it can result in more accurate results.

The surface element method is a kind of boundary element method, and its basic idea is to transform the Laplace equation of the incompressible, inviscid, and irrotational potential flow problem into an integral equation on the boundary by using Green formula. Thus, the flow around a three-dimensional object is transformed into the solution of the unknown singular point plane distribution on any object surface.

The viscous flow method using RANS equation is to directly solve the RANS equation method to obtain the propeller viscous flow field, so as to obtain the propeller hydrodynamic performance parameters.

FINE/Marine, Fluent, etc., are commonly available software.

Principles of Open Water Test

The advance speed and rotation speed of the propeller model are obtained according to the similarity theorem of the propeller including geometric similarity, kinematic similarity, and dynamic similarity. The advance coefficient, Reynolds number, and Froude number are presented with dimension analysis method.

$$J = \frac{V_A}{nD}$$

$$R_n = \frac{V_A L}{\nu}$$

$$F_r = \frac{V_A}{\sqrt{gL}}$$

$$K_T = \frac{T}{\rho n^2 D^4}$$

$$K_Q = \frac{Q}{\rho n^2 D^5}$$

$$\eta_0 = \frac{K_T}{K_Q} \cdot \frac{J}{2\pi}$$

J represents the advance coefficient. K_T is the symbol of thrust coefficient and K_Q is the symbol of torque coefficient. η_0 represents the open water efficiency.

The similarity theorem is satisfied when the three parts of the propeller and the model are equal. Furthermore, the effect of the wave is negligible when the paddle shaft is at a certain depth underwater, and the Froude number representing gravity similarity is abandoned. In addition, when the critical Reynolds number (3×10^5) is met, the influence of viscosity can be ignored. However, the scale effect needs to be considered.

Open water characteristics are frequently determined from model experiments on propellers run at high-speed and having diameters of the order of 200–300 mm (Carlton 2012). It is, therefore, reasonable to pose the question of how the reduction in propeller speed and increase in diameter at full-scale will affect the propeller performance characteristics (Carlton 2012). Figure 2 shows the principal features of scale effect, from which it can be seen that the torque coefficient is somewhat reduced for a given advance coefficient while the thrust characteristic is largely unaffected (Carlton 2012).

The scale effects affecting performance characteristics are essentially viscous in nature and are primarily due to boundary layer phenomena dependent on Reynolds number (Carlton 2012). Due to the methods of testing model propellers and the consequent changes in Reynolds number between model and full-scale, or indeed a smaller model and a larger model, there can arise a different boundary layer structure to the flow over the blades (Carlton 2012). While it is generally recognized that most full-scale propellers will have a primarily turbulent flow over the blade surface, this need not be the case for the model where

Open Water Test,**Fig. 2** The principal features of scale effect

characteristics related to laminar flow can prevail over significant parts of the blade (Carlton 2012).

In order to quantify the scale effect on the performance characteristics of a propeller, an analytical procedure is required (Carlton 2012). There is, however, no universal agreement as to which is the best procedure. In a survey conducted by the 1987 ITTC, it was shown that from a sample of 22 organizations, 41 percent used the ITTC–1978 procedure; 23% made corrections based on correlation factors developed from experience; 13%, who dealt with vessels having open shafts and struts, made no correction at all; a further 13% endeavored to scale each propulsion coefficient, while the final 10% scaled the open water test data and then used the estimated full-scale advance coefficient (Carlton 2012).

Hence, similarity theorem is all about kinematic similarity, implemented through equalizing the advance coefficient of the propeller and model.

$$K_T = f_1(J)$$

$$K_Q = f_2(J)$$

There are two ways to obtain the advance coefficient: In the towing tank, the model rotational

speed is kept constant and the advance speed is changed; in the cavitation tunnel, the advance speed of the model remains still and the rotational speed is changed. The thrust coefficient, torque coefficient, and open water efficiency under different advance coefficients were obtained through experiments and plotted as the propeller characteristic curves (Zhu 2016).

The main measuring device for the open water test is data acquisition system and propeller dynamometer, which is classified as a mechanical dynamometer (shown in Fig. 3), electric test dynamometer, and electromechanical integrated dynamometer due to the different power sources. The data acquisition system consists of two parts. One part is a data collection device, which measures data by an open water dynamometer machine and transmutes to the data collection device for filtering, amplifying, and processing. The other part is data acquisition system supporting software. The data acquisition device is connected to a computer with software, which will be processed in the back of the data input, and the software will be able to visualize and move on to the data. At the same time, the software is also a platform for the operation of data acquisition equipment, with the control of data acquisition, system balance, and other functions.

Open Water Test, Fig. 3 J04 Propeller Dynamometer (mechanical dynamometer)

In the preparation stage of the test, the whole set of test equipment including open water dynamometer and data acquisition system is tested and calibrated to obtain the calibrated value. Besides, in the open water test, the rotational speed and advance speed of the propeller should be determined first. The selection of these two values is very important. First of all, the rotation speed of the propeller should take into account the influence of factors such as the material of the propeller itself, and the selection of the advance speed should take into account the influence of factors such as the performance of the trailer. The interval of the advance speed shall not be too large. Otherwise, the test data points will be too small, which will not be able to accurately reflect the trend of the water performance curve of the open water. On the contrary, the interval will be too small to increase the number of tests. Then the experiment can be carried out with the change of advance speed.

During the test in the cavitation test tube, the similarity condition must be satisfied that the number of cavitation is equal as well as the coefficient of advance. The cavitation test cylinder is composed of a sealed circulating water cylinder, a driving water pump, a pressure regulating device, and so on. There is an observation window in the working section, and throughout the test, water circulates and is depressed to make the number of cavitation equal to the number of the real

propellers. The test process is observed and recorded with stroboscope and high-speed camera, and the thrust, torque, and other test data of propeller are measured by dynamometer.

Propeller tests (open-water tests, cavitation tests) are usually performed in cavitation tunnels (Bertram 2012). A cavitation tunnel is a closed channel in the vertical plane recirculating water by means of an impeller in the lower horizontal part (Bertram 2012). In this way, the high hydrostatic pressure ensures that even for reduced pressure in the tunnel, the impeller itself will not cavitate (Bertram 2012). The actual test section is in the upper horizontal part. The test section is provided with observation glass ports (Bertram 2012). The tunnels are designed to give (almost) uniform flow as inflow to the test section. If just the propeller is tested (with the driving shaft downstream), it is adequately tested in open water (Bertram 2012).

Vacuum pumps reduce the pressure in the tunnel and usually some devices are installed to reduce the amount of dissolved air and gas in the water. Wire screens may be installed to generate the desired amount of turbulence (Bertram 2012).

Cavitation tunnels are equipped with stroboscopic lights that illuminate the propeller intermittently such that propeller blades are always seen at the same position (Bertram 2012). The eye then perceives the propeller and cavitation patterns on each blade as stationary (Bertram 2012).

Usual cavitation tunnels have too much background noise to observe or measure the noise-making or hydro-acoustic properties of a propeller, which are of great interest for certain propellers, especially for submarines or anti-submarine combatants (Bertram 2012). Several dedicated hydro-acoustic tunnels have been built worldwide to allow acoustical measurements. The HYKAT (hydroacoustic cavitation tunnel) of HSWA is one of these (Bertram 2012).

Key Applications

The open water test is mainly used to measure the hydrodynamic performance of various propellers, such as ducted propellers, pod propellers, and combined propellers. It is also sometimes used to measure hydrodynamic characteristics of rudder and other attachments, such as the open-water test of a connecting rod flap rudder (Zhu 2013).

Open Water Test of Pod Propellers

Ever since the concept of pod propeller was proposed, after more than 20 years of development, it has been successfully applied in many ship types. Its excellent performance, which has been shown in practical applications, attracts more and more ship-owner and ship designers' concerns, as well as more and more attention to their research on hydrodynamic performance. The open water test for the pod thrusters is to test the entire pod parts, including the propeller, the pod, the stents, and the fins, as part of the propulsion unit, and the open water test for the pod unit requires the development of a specialized testing device. The complete open water test of pod propeller not only measures the thrust and torque of a propeller, but also measures the thrust of the whole pod unit (Shen 2007). The characteristic quantities such as the lateral force and the rudder moment of the whole unit can be investigated more completely. The dynamometer includes propeller dynamometer and unit force balance. The thrust and torque of the propeller are measured by a dynamometer located in the cabin. The axial force, lateral force, and rudder torque of the whole unit are measured by a three-component force balance. Besides, the

propeller is driven by a motor through a driving shaft. Water tightness is considered in the design of the dynamometer and transmission mechanism as well. The whole test device is composed of free stress part and fixed constraint part. The free force part consists of propeller, cabin, bracket, tail fin, and other parts. The force is measured by propeller dynamometer and three-component balance. It is important that free-stressed parts are not affected by other test equipment. The fixed restraint is secured to the trailer and should be avoided that the force on it affects the balance measurement. The test apparatus is capable of accurately adjusting the submerged depth of the propeller shaft in the subsea and ensuring that the paddle axis is parallel to the horizontal plane. Combined with the test results of the pool and other relevant data analysis, it is concluded that in the open water test of the pod propeller, the bracket clearance should be kept as small as possible, and the hub clearance should be controlled in an appropriate range.

Open Water Test of Combined Propellers

Compared with common propellers, combined propellers have the great advantage of reducing the radiation noise of propellers, improving the efficiency of open water and the initial critical speed of cavitation. At the same time, if the propeller can match the hull properly, it can even obtain higher propulsion efficiency. The structural features of such thrusters are multicomponent combinations, so that the characteristics of hydrodynamic interference among components will be the focus of their performance research. In order to study the hydrodynamic interaction between the components of the combined propeller, the method of decomposition test may be employed.

New Scientific Discovery

Changes in Testing Methods

By using the traditional test method, on the one hand, it needs to be operated by many people, and it is easy to bring artificial reading error, and on the other hand, processing the data of these measurements is quite a time-consuming and

laborious work. With the rapid development of computer technology, a variety of electrical measuring sensors have appeared continuously, which provides convenient conditions for the computerization of open water test. By using the computer to collect and process the data, we can analyze and modify the program in real-time, reduce the error, and realize the automatic control of the experiment process.

Digital signal processor (DSP); Fiber-optic gyro (FOG); Fiber-optic gyro attitude reference system; Fiber-optic gyro motion sensor; Inertial measurement unit (IMU); Motion reference unit (MRU); Strapdown inertial navigation system (SINS)

Definition

Fiber-optic gyro compass is a strapdown inertial navigation system (SINS) with three fiber-optic gyros and three accelerometers. This compass outputs the information of the heading, roll, and pitch. Comparing to the traditional mechanical gyro compass, fiber-optic gyro compass has less setting time, higher measuring accuracy, better dynamic characteristics, and longer service life. It is specially suitable for the navigation and control of high-speed platforms with high rate of turn.

Scientific Fundamentals

Frame Definitions

A fiber-optic gyro compass relates to several basic navigation frames (Li et al. 2013) drawn in Fig. 1.

1. The b-frame. Body frame, the strapdown inertial sensor frame, with its origin at the center of mass of the accelerometer and gyro triad and

Optical Compass,**Fig. 1** The frames definition

axes parallel to nominal right-handed orthogonal sensors input axes.

2. The i-frame. Inertial frame, stabilized in the inertial space.
3. The n -frame. Navigation frame is the local level coordinate frame here. Its x axis points to East (E), y axis points to North (N), and z axis points upward (U).

Fiber-Optic Gyro

In a fiber-optic gyro compass, fiber-optic gyro (FOG) is used for measuring the rotation angle. Recently, FOG is being widely used for military and defense applications, due to its significant advantages such as small size, low cost, light weight, no moving parts, large dynamic range, low power consumption, and possible batch fabrication (Narasimhappa et al. 2014).

FOG is a kind of optical gyros and its principle is based on the Sagnac effect, as shown in Fig. 2. After passing through the coupler, the light beam from SLD source is divided into two light beams by the polarizer. The two light beams propagate along the two opposite optical paths in the fiber-

optic ring. If there is no angular velocity ($\Omega = 0$), the CW light beam and CCW light beam arrive the detector simultaneously and interfere with each other. The detector could convert the light intensity of interference into electrical signals. If there is one angular velocity ($\Omega \neq 0$), the output of the detector will be changed. The polarizer could also modulate the phase of the light beam by applying voltages to improve the angular velocity detection.

The performance of FOG degrades due to the variation in environmental factors such as temperature, vibration, and pressure. Among different types of error in the FOG signal, random drift error leads to decrease the FOG performance over a period of time. The precision of FOG depends on the bias drift and noise in the measurement. FOG has mainly two types of error (i) deterministic error and (ii) stochastic error. Deterministic errors are due to the scale factor, bias, and misalignment which can be eliminated by suitable calibration techniques in the laboratory environment. However, stochastic errors are due to the environmental temperature changes, electronic components, and other electronic equipment interfaced with it. It is difficult to

Optical Compass,

Fig. 2 Basic structure of the fiber-optic gyro

eliminate these errors by calibration. Thus, stochastic models are required to characterize these errors, and signal processing techniques are required to suppress these errors.

Working Principle

In favor of modern technologies, gyrocompass manufacturers have abandoned gimballed platform and mechanical gyros, and began to use mathematic platform and optical gyros instead. Comparing to the traditional mechanical gyro compass, fiber-optic gyro compass has less setting time, higher measuring accuracy, and better dynamic characteristics. It is specially suitable for the navigation and control of high-speed platforms. Because of the solid-state solution, the strapdown gyro compass has high reliability and is maintenance-free during its service life. Thus, strapdown gyro compass is the current and next-generation marine navigator to provide attitude measurements.

The heart of a fiber-optic gyro compass is its inertial measurement unit (IMU), whose mechanism is composed of three orthogonal fiber-optic gyros and three orthogonal accelerometers. As depicted in Fig. 3, a full range IMU corresponding to the three axes of the ship b -frame system will measure six degrees of freedom movement relative to n -frame system including the three rotational moments (pitch, roll, and yaw) and the three translational moments (heave, surge, and sway).

The basic working principle of a fiber-optic gyro compass is the strapdown inertial navigation algorithm. A block diagram representation of this algorithm is shown in Fig. 4. Strapdown inertial

Optical Compass, Fig. 3 Fiber-optic gyro compass installed in ship

navigation system is a self-contained architecture that double integrates three acceleration components with respect to time and transforms them into the n -frame to deliver position, velocity, and attitude components in real time. The three orthogonal linear accelerations are continuously measured through three-axis accelerometers while three gyroscopes sensors measure the three orthogonal angular rates in an inertial reference frame. Digital signal processor (DSP) is used to calculate the mathematic platform.

For short time, the integration with respect to time of the linear acceleration and angular velocity monitored by the gyroscopes results in accurate attitude, position, and velocity. However, sensor errors and mathematical integration over a long time of the fiber-optic gyro compass may

The relationship between the navigation frame and the body frame is realized by continuously updating this attitude matrix. To limit the errors in the derived navigation parameters, it is very important to determine the initial value of such matrix with high accuracy.

In static ground alignment, the system attitude can be determined directly by using the gravity and earth rate signals obtained by using accelerometers and gyros in the navigation frame. However, the swing of marine will be caused by the wind wave. During the alignment process of SINS, gyros are employed to monitor the components of the earth rotation rate along their sensitive axes to determine the initial attitude of the moving platform. The angular rate error which is decided by the wind wave is much larger than Earth rate. So, the signal-to-noise ratio of gyro's output is poor, and the frequency band of angular rate error is wide. It is impossible to directly get the Earth rate from gyros. Therefore, a feasible alignment solution for marine SINS may not only use the Earth rate and gravity obtained by using gyros and accelerometers, but also use some external information (GPS, LOG, etc.) (Sun and Sun 2010).

The alignment process of compass is generally divided into two steps: coarse alignment and fine alignment. The goal of the coarse alignment stage is to solve the rough coordinate transformation matrix from the carrier system to the navigation system as soon as possible, which provides a good initial condition for the fine alignment stage. Therefore, rapidity is the main performance design index in the coarse alignment process. Generally, there are some errors between the attitude matrix obtained by coarse alignment and the real navigation system, especially the error of heading angle, which is much bigger than the error of horizontal attitude. In addition, the errors of inertial devices, such as the constant drift of gyroscope, will lead to the deterioration of the performance of navigation equipment after the start-up of the equipment. It is usually necessary to estimate and compensate for these errors in the process of fine alignment. The aim of fine alignment is to obtain the attitude angle which is infinitely close to the real value and compensate for

other errors in the alignment process. Accuracy and rapidity are the two most important indicators of fine alignment.

Damping Technology of Strapdown Compass

In strapdown solution, in order to avoid the influence of acceleration information on accelerometer data, it is necessary to select appropriate system parameters to make the system meet Schuler tuning conditions which are the undamped working state. However, when the system works in the undamped state, there are three kinds of oscillation errors caused by various kinds of disturbances. The three kinds are Schuler oscillation error with a period of 84.4 min, Foucault oscillation error with latitude variation, and Earth oscillation error with a period of 24 h. Among those oscillation errors, Foucault oscillation error and Schuler periodic oscillation error are mutually modulated. Those oscillation errors will lead to oscillation errors of navigation parameters in pure inertia solution, and even divergence of navigation errors in long-term operation. Those oscillation errors cannot be ignored. Therefore, in practical applications, the strapdown compass is usually switched between undamped and damped states according to different sea conditions.

There are two main working states of a fiber-optic gyro compass: undamped state and damped state. The fiber-optic gyro compass normally works in the damped state which is also called compass state. The compass-loop control is used to find the north and indicate the ship's course and attitude information. When the ship encounters strong motions such as bad sea conditions or frequent velocity variations, the disturbance motion information is measured by accelerometer, and then controlled by compass channel as part of gravity. In order to reduce the impact of external maneuvering environment on the compass output, the fiber-optic gyro compass needs to enter the undamped state in a short time.

A general way to compensate the maneuvering error caused by the motion of the carrier is the "broken pendulum" often used in the platform compass system. This way refers to the accelerometer measurement data. If the sensitive data exceeds one threshold, the fiber-optic gyro

compass will not calculate the attitude information based on the accelerometer data. Therefore, the interference of errors caused by the acceleration of carrier maneuver can be overcome by an appropriate threshold.

Integrated Navigation Technology

With the rapid development of the fiber-optic gyro, the fiber-optic gyro compass will be more accurate, smaller in size, more reliable, cheaper, and lower in energy consumption. However, the navigation error of the fiber-optic gyro compass will accumulate over time, which is difficult to meet the long-distance and long-time navigation requirements. Therefore, the external navigation information from other navigation systems is necessary for the fiber-optic gyro compass to correct the diffuse system error.

The common working principle of an integrated navigation system is shown in Fig. 5. Each navigation system provides corresponding navigation information, which is fused by filtering method to obtain more accurate and reliable navigation information. According to different application

environment and requirement, one or more other navigation modules are chosen for an integrated navigation. The general process of building integrated navigation system can be described as follows: by modeling and analyzing the system structure abstractly, the state equation and measurement equation of the system are established, and the state information or state error information of the system is estimated optimally by Kalman filter, and the optimal estimation is used to correct the navigation parameter information of subsystems.

Typical Applications

Navigation

At sea, mechanical gyro compass has always been used as a source of course information for ships. The mechanical gyros can sense the angular deviation of the navigation reference coordinate system relative to the inertial coordinate system, and provide this signal to navigation and positioning systems. It can be applied to the satellite positioner ARPA, integrated navigation system,

Optical Compass,
Fig. 5 The principle of integrated navigation system

AIS, etc. The improvement of the mechanical gyro accuracy is seriously restricted by the unbalanced mass of the high-speed rotating “rotor,” the cross-coupling effect of the rotational degrees of freedom, the moment of inertia of the rotor, the harmful moment of the rotor support, and other factors. Also, the start-up time of the mechanical gyro compass is up to 6 h long. The fiber-optic gyro compass is not affected by this aspect. In addition to providing high-precision course information, it can also provide information of pitch, roll, and ship rotation angular velocity. The fiber-optic gyro compass hardly needs start-up time. Therefore, it will replace the mechanical gyro compass and be widely used in navigation.

Survey

With the increasing demand for understanding underwater topography and geomorphology, multi-beam bathymetry system is becoming more and more popular as an underwater topographic survey system with the advantages of full coverage, high efficiency, high precision, and high resolution. It has been widely used in underwater completion survey, pipeline route survey, breakwater mapping, before dredging and after dredging survey, coastal zone mapping, revetment survey, port mapping, river survey, IHO special survey, search and rescue, site obstacle survey, pipeline inspection, underwater inspection, object positioning, etc. When Multi-beam bathymetric system is used for bathymetric survey, due to the influence of wind and wave, the surveying ship will inevitably produce three rotational moments (pitch, roll, and yaw) and the three translational moments (heave, surge, and sway), which will lead to the inclination of the coordinate system of the surveying ship and the systematic deviation of the measured water depth. A fiber-optic gyro compass can provide six-degree-of-freedom motion information for ship measurement, and assist multi-beam bathymetric system to make systematic correction.

Dynamic Positioning

Dynamic positioning ship has become one of the most important marine equipment in the ocean engineering, which consists of measuring,

propulsion, and control devices. The accuracy of measurement system has a great influence on the accuracy of ship positioning control. A fiber-optic gyro compass could be used as a motion reference unit (MRU) to measure the ship’s motion. It measures the roll, pitch, and heave of the ship or platform during operation. Comparing the measured data with the preset values, the control system generates control instructions to keep the ship’s position.

Synonyms

Design optimization; Optimized design; Optimum design

Definition

Optimal design is usually considered as the design process that seeks the “best” possible solution(s) for a mechanical structure, device, or system, satisfying the requirements and leading to the “best” performance, through optimization techniques. It also refers to the design points that best satisfy objective(s) which are in contrast to non-optimal design. George Dieter has given a formal definition of **design** as follows: “Design establishes and defines solutions to pertinent structures for problems not solved before, or new solutions to problems which have previously been solved in a different way” (Dieter and Schmidt 2009). **Optimal** indicates a searching and decision-making process that is required to determine the best possible design alternatives. Optimization techniques are used to evaluate the trade-off among design alternatives and determine the best one(s).

Scientific Fundamentals

Brief Background

Engineering design process can be viewed as a sequential process. The sequence of design operations includes exploring alternative concepts, formulating a mathematical model, specifying specific subsystems, etc., while the design of complex systems can be broken down into a sequence of design steps. Design solutions come out as a result of repeated trials and errors. With the help

of computer technologies, time-consuming and repetitive operations, like experiments, are replaced by computer program or simulations. Complex problems can be analyzed faster, and designers’ capabilities are extended.

The importance of optimal design has been realized in 1980s since the high-quality products from Japanese companies invaded the market of the western world. Mathematical fundamentals for the design process have been developed for a long time, and it is still on its way to maturity. The best way to achieve high quality in a product is to design it from the beginning and assure that it is maintained throughout the manufacturing process. The enemy of quality is variability in performance and manufacturing. In this case, *robust design* has arisen to reduce variability while simultaneously leading the performance toward the optimal design point (Dieter and Schmidt 2009).

To guarantee the product quality, the concept of quality control arose. All actions taken throughout the engineering and manufacturing of a product to prevent and detect product deficiencies and product safety hazards can be regarded as **quality control**. According to the “80/20 rule,” it is clever to concentrate on the vital few causes that worsen the product quality. *Cause-and-effect analysis diagram* can be used to identify possible causes of a problem. **Control chart** is an important quality control tool, which collects and keeps performance data for detecting variations.

Since there is more than one possible solution to a design problem, the need for optimization is inherent in a design process. Design optimization methods in engineering design can be summarized by four broad categories: by evolution, by intuition, by trial-and-error modeling, and by numerical algorithms. There is no one universal optimization method for engineering design problems, and different kinds of methods fit for different problems. Computer-aided optimal design (or to be more specific, design optimization) generally starts with an initial or existing design point, and numerical analysis is used afterward to calculate the performance measurements and the sensitivity of the performance measurements with regard to uncertainties in design parameters.

New design candidates will be generated during the running of optimization algorithms, while optimum design(s) will be achieved after the execution of the optimization. It is worth mentioning that although we often use “optimal design” and “design optimization” interchangeably, they are not strictly equivalent. The former one usually refers to the whole design process or the optimal solution itself, while the latter usually refers to one important step in the design process or technology used to achieve the design solution(s).

Principles of Optimal Design

Design System

Designing is a systematic work. A design solution is also called a system (Arora 2004). An original system can be made up of several components which are also systems with their own functions and input/output characteristics, as shown in the diagram in Fig. 1. That is to say, a system can usually be decomposed into interconnected subsystems, which can be further broken down and analyzed at a particular but lower level of complexity. For example, a gas-turbine system contains the components, e.g., compressor, combustor, turbine, etc. Each of the components is a complicated system itself. Meanwhile, the gas-turbine system is just one component of a petroleum plant. It is of vital importance to decide whether to represent the design task as a unit or as a collection of components (subsystems).

Mathematical Model

Engineers always use an abstract representation instead of a real system for the purpose of analysis. An abstract description of the real-world system is called a model, which provides an approximate representation of a physical system

with complex functions. Mathematical models have been widely accepted and applied in representing design systems through mathematical relations. The system, as shown in Fig. 1, can be represented by $y = f(x)$, where x , y represent the vectors of input and output quantities, respectively, and f can be equations, algebraic or differential, or a computer-based simulation program.

To model a system, we need to generalize the design problem and identify the following model elements: system variables, system parameters, system constants, and mathematical relations. *System variables* specify different states of the system by assigning different values. *System parameters* are assigned with one specific value in one particular model statement and can be used to take care of uncertainty or variations when considering robust design. *System constants* are fixed by underlying phenomenon which cannot be influenced by the designers. *Mathematical relations* relate to the system variables, parameters and constants using equalities and inequalities, or even implicit formulations. Determination between variables and parameters is subjective but important at the modeling stage. To model a design mathematically, we must be able to define it completely by assigning values to each quantity involved, such as geometric configuration, the material used, and the task it performs. A design modeling study will help increase our understanding on how a system works.

Decision-Making and Design Optimization

A design process can generate more than one alternative in general. A need for making a decision on choosing one or a few of them in this case arises. To evaluate different alternatives and rank them in a rational order, at least one criterion is required. Such criterion may not be unique or may change with time. The design model with the evaluation criterion is a decision-making model or an optimization model. The criterion is called the *objective* of the model, and the selected “best” design is called *optimal design*. Design optimization is to select the “best” design solution (s) according to available requirements.

To quantitatively formulate a design optimization problem and solve it, a mathematical

Optimal Design, Fig. 1 Design system diagram

Optimal Design,**Fig. 2** Local and global optima

representation is built. $\mathbf{x} = (x_1, x_2, \dots, x_n)^T$, in a n -dimensional design space, is the vector of *design variables* whose value describe a design alternative. The acceptable limits on $\mathbf{x}$ are called *lower* and *upper* bounds. The objective is represented by a function of design variable, $f(\mathbf{x})$. It is possible that there are multiple objectives in one design optimization problem too. In that case, there will be multiple objective functions, like $f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_m(\mathbf{x})$. Available requirements are *constraints* by the function relationship among $\mathbf{x}$. $h_k(\mathbf{x}) = 0, k = 1, \dots, K$ and $g_j(\mathbf{x}) \leq 0, j = 1, \dots, J$ represent equality and inequality constraints, respectively. Any design satisfying the constraints contributes to the *feasible design space*. Different forms for f, g_j , and h_k are usually derived from basic equations and engineering laws. Also they can be derived through curve fitting using empirical or experimental data or through simulation modeling, which is the current statement of the complex procedure involving internal calculations and computer programs. In practice, mathematical models in design optimization can be a mixture of above. Then the design optimization problem is formulated as

$$\begin{aligned} & \min_{\mathbf{x}} f(\mathbf{x}) \\ & \text{s.t. } g(\mathbf{x}) \leq 0 \\ & \quad h(\mathbf{x}) = 0 \\ & \text{where } \mathbf{x} = [x_1, x_2, \dots, x_n]^T \end{aligned} \quad (1)$$

Design optimization involves the selection of design objectives, determination of constraints, and the set of design variables that optimize the objective(s) while satisfying all constraints.

A complete optimization study to find the optimal design(s) could be expensive and time-consuming for large systems. Thus, several iterations, instead of a complete optimization study, are performed until sufficient improvement in the design has been obtained.

Local and Global Optima

As shown in Fig. 2, point B and E (point C and F) are minima (maxima) with regard to the values in the local vicinity. They are called *local minimum* (*local maximum*). The boundary points A and G are also taken into consideration when determining the overall optimum. From all local minima (local maxima) and boundary points, the smallest one is defined as the *global minimum* (*global maximum*). It can be observed that both local and global optima may not be unique. Sometimes an infinity of solutions may be detected.

Finding global solutions to optimization problems is important for design optimization. However there is yet no universal solution strategy proven by general optimization theory in practice.

To identify the global optimum, a thorough study is conducted to go through all the local optima and determine the global one even under different ranges of parameters. However, this may be difficult from the mathematical viewpoint or expensive from the computational viewpoint.

Mathematical methods can be used to identify the solution(s) to the problem. However, to address the solving task in a purely mathematical way while divorcing from the physical significance of the model and its elements can be a tactical error. Optimization problems in design are generally difficult to solve mathematically.

On the contrary, the “best” design solutions may not need to be mathematically proven optima. Typical solving methods in mathematical programming use iterative numerical search procedures. Starting from an initial point, the direction of improvement is identified, and a step is taken along that direction. Consequently, a sequence of points that converge to the minimum can be created. Such numerical iterative computation is driven by local knowledge, which is easy to get but has limited ranges. Global knowledge is superior and results in better techniques but difficult to acquire.

Optimization Methods

Analytical Optimization Methods *Graphical optimization* is a method that finds the optimum solution by drawing the objectives and constraints graphically. Since the graphics can only be drawn on a two-dimensional space, this method can only be used to solve the problems with two design variables. To obtain the optimum solution, the constraints are drawn on the two-dimensional design variable space which forms the feasible region. Then by drawing the iso-objective contours, the design point that makes the objective function reach the minimum in the feasible region is identified as the optimum point. Due to its property and limitations, this method is useful for the illustration of optimization methods.

Optimization problems without constraints are called *unconstrained optimization problems*. For this kind, there exist necessary and sufficient conditions for local minimum.

Necessary condition: if $f(\mathbf{x})$ has local minimum at point $\mathbf{x}^*$, then the gradient of $f(\mathbf{x})$ at $\mathbf{x}^*$ is 0.

$$\nabla f(\mathbf{x}^*) = \mathbf{0} \quad (2)$$

Sufficient condition: if the Hessian matrix $\mathbf{H}(\mathbf{x}^*)$ is positive definite at $\mathbf{x}^*$, then $\mathbf{x}^*$ is sufficiently a local minimum.

To obtain a local minimum for a function $f(\mathbf{x})$, which is the objective of an unconstrained problem, we first obtain a solution $\mathbf{x}^*$ satisfying Eq. (2). Then we check if the Hessian matrix is positive definite at $\mathbf{x}^*$. If its Hessian matrix is

positive semidefinite, higher order derivatives need to be checked.

For *constrained optimization* problem, an optimum point can be mathematically obtained using the theorem called Karush-Kuhn-Tucker (KKT) condition. The constraints are added to the objective function by multiplying each with a Lagrange multiplier, resulting in a Lagrange function. The gradient vector of Lagrange function with regard to the design vector $\mathbf{x}$ and Lagrange multipliers becomes a zero vector at local minimum. Original constraints and additional restrictions for Lagrange multipliers should be satisfied. More details about KKT condition can be found in the reference (von Laarhoven and Aarts 1987). If the objective $f(\mathbf{x})$ is a convex function defined on a convex feasible domain, the prementioned KKT condition is both necessary and sufficient condition for a global optimum.

Numerical Optimization Methods In real practice, finding the optimum solution(s) through mathematical calculations is quite difficult. It is often difficult to solve simultaneous equations which make the gradient vector be a zero vector. Besides, as the number of constraints increases, the process to evaluate many cases in KKT condition for inequality constraints becomes more complicated. It is almost impossible to solve a design optimization problem with mathematical calculations when many constraints exist in the problem. Instead, *numerical methods* using computer programming are utilized. Various numerical methods are developed specifically for different problems.

Numerical methods start from an initial design point and find an optimum in an iterative way. At each iteration, a new design is found. When at least one of the convergence criteria is satisfied, the design in the current iteration is considered as an optimum. The design is improved at each iteration through Eq. (3).

$$\mathbf{x}^{(k+1)} = \mathbf{x}^{(k)} + \Delta \mathbf{x}^{(k)}, k = 0, 1, 2, \dots \quad (3)$$

where k is the iteration number. A new design $\mathbf{x}^{(k+1)}$ is obtained by adding the change of design vector $\Delta \mathbf{x}^{(k)}$ to the current design $\mathbf{x}^{(k)}$. The change $\Delta \mathbf{x}^{(k)}$

consists of the moving direction $\mathbf{d}^{(k)}$ at the point $\mathbf{x}^{(k)}$ in the design space and the scalar step size α_k in the direction $\mathbf{d}^{(k)}$.

$$\Delta \mathbf{x}^{(k)} = \alpha_k \mathbf{d}^{(k)} \quad (4)$$

The evaluation of α_k and $\mathbf{d}^{(k)}$ depends on the algorithm used. The determination of α_k and $\mathbf{d}^{(k)}$ should reduce the objective function $f(\mathbf{x}^{(k)})$ when $\mathbf{x}^{(k)}$ is not an optimum yet. This condition is expressed as in Eq. (5).

$$f(\mathbf{x}^{(k+1)}) = f(\mathbf{x}^{(k)} + \alpha_k \mathbf{d}^{(k)}) < f(\mathbf{x}^{(k)}) \quad (5)$$

The sensitivity information, i.e., the (partial) derivative of objective and constraint functions, is used to decide the descent direction in numerical methods. Mathematical derivative functions or finite difference method can be used depending on different situations.

The overall steps of a numerical procedure are shown in Fig. 3.

Heuristic Optimization Methods Heuristic optimization algorithms are developed by observing different nature behaviors. They are different from classic optimization methods like gradient-

based approaches. The search process proceeds toward a solution(s) without caring how the functions are evaluated. Thus continuity or differentiability of the problem functions is not required. In addition, the methods inherently try to determine the global optimum. Since no gradient information is required, heuristic methods are easy to use and program. However, such algorithms usually require a large amount of calculations, and there is no guarantee of obtaining the global optimum.

Genetic algorithms (GA) and simulated annealing (SA) are two popular heuristic methods. GA are based on Darwin's theory of natural selection. The basic idea is to start with a set of randomly generated designs. A fitness value is assigned to each design by using its values of the objective function and penalty function for constrained problems. Processes (e.g., reproduction, crossover, and mutation) which can generate new designs with certain randomness are used to generate new designs. The size of the design set in one iteration is kept fixed, called the population. As more fit members of the set are used to create new designs, the successive sets of designs will have a higher probability of involving better fitness values. The process is continued until a stopping criterion is met. A flowchart of GA is shown

Optimal Design,
Fig. 3 General steps of
numerical method

Optimal Design,
Fig. 4 Flowchart of GA

in Fig. 4, representing a general procedure of this algorithm. The details of each step can be found in the literature (Arora 2004). The length of strings (used to represent each design) and population size are decided in the initialization stage. The fitness evaluation determines how “good” design points will be in the population. The three operations, reproduction, crossover, and mutation, make more copies of better designs and remove worse designs gradually. New designs with better quality are generated. They also provide GA the capability of jumping out from the local optimum. Designs will converge to the optimal solutions iteration by iteration.

SA is a computational stochastic technique for obtaining the global optimum. It is inspired by the thermodynamic process of annealing of molten metals to attain the lowest free energy state. When the metal is cooled slowly enough, it tends to solidify into a structure with the minimum energy. SA is a search strategy imitating the annealing process. The key of the method is to allow occasional worsening moves which may eventually help locate the design to the true global optimum. Details of SA can be found in (von Laarhoven and Aarts 1987). When setting up the problem, the appropriate initial temperature is required. New designs are generated by perturbation, and function values are evaluated. The new

design is accepted for sure if it is a better point, or it is accepted by probability if it is a worse design. The temperature is slowly reduced. Optimal solutions will be gradually reached through the SA procedure.

Multi-criteria and Multidisciplinary Design

If there is a set of criteria, $\mathbf{f} = (f_1, f_2, \dots, f_m)^T$, the design problem becomes a multi-criteria one:

$$\begin{aligned} & \min_{\mathbf{x}} \mathbf{f}(\mathbf{x}) \\ & \text{s.t. } g_j(\mathbf{x}) \leq 0, j = 1, \dots, J \\ & \quad h_k(\mathbf{x}) = 0, k = 1, \dots, K \end{aligned} \quad (6)$$

Several methods exist to convert the multi-criteria formulation into a substitute single-criterion problem which can be solved by single-objective optimization methods. The simplest scalar substitution is obtained by assigning subjective weights, $\mathbf{w} = (w_1, w_2, \dots, w_m)^T$, for multiple criteria, and the set of objectives are translated into a scalar $f = \sum_i w_i f_i(\mathbf{x})$. The weights can be considered as the design preference that can be adjusted according to designers’ preferences or different usage scenarios. For example, different combinations of preference parameters can represent different levels of trade-offs among those criteria. The solution set discovered by assigning different weights can form the

so-called Pareto set, which includes solutions that cannot improve one criterion without sacrificing others, as shown in Fig. 5. Other approaches suitable for multi-criteria design problems can be found in literature, like value-function method, goal programming (Ignizio 1976), game theory (Vincent 1983), and upper-bound formulation.

As discussed above, a system can be decomposed into different levels of subsystems. The designer must identify at which level the

design optimal solutions are required, while it is possible that the design optima of subsystems (without considering other subsystems) may not be optimum for the entire system. For example, the GnC, vehicle body, and engine are three subsystems of an undersea vehicle system. The optimum design of the GnC may not be the best solution for the entire vehicle if not considering the design of the vehicle body or engine. For large-scale problems, treating the system as a single entity may encounter difficulties for reliable solutions. Instead, the problem can be modeled by a set of independent subproblems which are coordinated by a master problem (or called system problem). Design variables associated with the master problem are called *global variables*, while those associated with subproblems are *local variables*. *Linking variables* are used to represent the original couplings between subproblems. Hierarchical and nonhierarchical partitioning of a system are shown in Figs. 6 and 7, respectively.

Decomposition-based approaches for system design require both portioning and coordination. They are employed to improve the overall

Optimal Design, Fig. 5 Feasible domain and Pareto set of bi-criteria optimization

Optimal Design, Fig. 6 Hierarchical decomposition

Optimal Design, Fig. 7 Nonhierarchical decomposition

solution efficiency. This branch of optimization design methods arises as multidisciplinary design optimization (MDO).

Robust Optimal Design

Robust design refers to the methods or procedures to develop system products whose performance is insensitive (or least sensitive) to the variations due to uncontrollable factors. As the pioneer of this research area, Taguchi first defined the loss function to evaluate the quality level of the products (Taguchi 1987). The smaller the loss, the more desirable the product. Taguchi method uses a special response variable, signal-to-noise ratio (S/N ratio), which encompasses both the mean and variation in one parameter. Design parameters that primarily affect the S/N ratio are identified, and the level of these parameters is found to minimize the response variations. Since lots of experiments are required in this parameter design, the fractional factorial design of experiments (DoE) is adopted instead of testing all combinations. Taguchi method is still popularly used in the practice although many drawbacks have been pointed out. Later, the robustness concept has been added to the conventional or so-called deterministic optimization. The objective and constraints functions are redefined with additional robustness indices. To distinguish the difference, the design variables determined by solving the conventional deterministic optimization problem

where variations (uncertainties) are not considered are called *nominal values* (or nominal solutions). *The robust optimal designs* come from the results of the robust optimization problem which takes variations into consideration. The robust optimization problem can be formulated as

$$\begin{aligned} \min_{\mathbf{x}} & f(\mathbf{x}, \mathbf{p}) \\ \text{s.t. } & g(\mathbf{x}, \mathbf{p}) \leq 0 \\ & \mathbf{x}_{lb} \leq \mathbf{x} \leq \mathbf{x}_{ub} \end{aligned} \quad (7)$$

where $\mathbf{p}$ represents the uncertainties in design variables or parameters.

One way of defining the robustness is shown as follows. *The robustness of the objective function* is achieved by reducing the variation in the objective function due to the uncertainties. As shown in Fig. 8, the objective function reaches its minimum at the point A. However, the objective value at this point will be influenced a lot by the small variation in the design variable. On the contrary, Point B and C are less sensitive to the uncertainty in the design variable, thus being more robust. *The robustness of the constraint functions* is defined such that all constraints should be satisfied whenever design variables or parameters are changing within their variation range.

In robust optimization, objective functions can be formulated in different ways. When uncertainties are modeled by probabilistic distributions,

Optimal Design,
Fig. 8 Nominal point
versus robust point

robust optimization problems can be formulated with the mean and the standard deviations in different ways, as shown below (Park et al. 2006).

Weighted Sum with Normalization

$$f_{\text{new}} = \alpha \frac{\mu_f(\mathbf{x}, \mathbf{p})}{\mu_f^*} + (1 - \alpha) \frac{\sigma_f(\mathbf{x}, \mathbf{p})}{\sigma_f^*} \quad (8)$$

The new objective function in the robust optimization can be formulated as the weighted sum of the mean and standard deviation of the original objective function f . α is the weighting factor between minimizing the objective value and minimizing the variation of the objective function. A smaller α value will put more emphasis on the robustness. μ_f^* and σ_f^* are the base values for the mean and standard deviation, respectively, used for normalization.

Bi-objective Formulation of Robust Optimization

$$f_{\text{new}} = \{\mu_f(\mathbf{x}, \mathbf{p}), \sigma_f(\mathbf{x}, \mathbf{p})\} \quad (9)$$

In this formulation, the mean value of the objective and its variation are optimized as two objectives simultaneously.

Constraint Formulation of Robust Optimization The constraint formulation of robust optimization can be shown as Eq. (10).

$$g_{\text{new}} = \mu_g(\mathbf{x}, \mathbf{p}) + k\sigma_g^2(\mathbf{x}, \mathbf{p}) \quad (10)$$

where k is a constant value which reflects the confidence level on the variation of the constraints. For example, when $k = 3$, the constraints will be satisfied with a probability of 99.865% with normal distributions.

When uncertainties are modeled by intervals, robust optimization can be formulated by using the definition of the robustness index (Li et al. 2006). The parameters $\mathbf{p}$ with interval uncertainty are represented by their nominal value $\mathbf{p}_0$, and the corresponding variation range $\pm\Delta\mathbf{p}$. $\mathbf{p}$ can take

any value randomly in the interval $[\mathbf{p}_0 - \Delta\mathbf{p}, \mathbf{p}_0 + \Delta\mathbf{p}]$ without any assumption on the distribution. The robustness of objective and constraint functions is quantified by using the robustness indices η_f, η_g , respectively.

$$\begin{aligned} & \min_{\mathbf{x}} f(\mathbf{x}, \mathbf{p}_0) \\ & \text{s.t. } g_j(\mathbf{x}, \mathbf{p}_0) \leq 0, j = 1, \dots, J \\ & \eta = \max \{\eta_f, \eta_g\} - 1 \leq 0 \\ & lb \leq \mathbf{x} \leq ub \end{aligned} \quad (11)$$

The robustness of the objective function under interval uncertainties are defined by Eq. (12). It says that the design $\mathbf{x}_0$ is objectively robust if the worst objective variation induced by $\mathbf{p}$ is within a predefined acceptable variation range Δf_0 .

$$\begin{aligned} \eta_f \leq 1 \quad \text{where } \eta_f &= \max_{\mathbf{p}} \left| \frac{f(\mathbf{x}_0, \mathbf{p}) - f(\mathbf{x}_0, \mathbf{p}_0)}{\Delta f_0} \right| \\ & \text{s.t. } \mathbf{p}_0 - \Delta\mathbf{p} \leq \mathbf{p} \leq \mathbf{p}_0 + \Delta\mathbf{p} \end{aligned} \quad (12)$$

Eq. (13) defines the robustness of constraints, which represents that $\mathbf{x}_0$ is feasibly robust if the worst increase of the constraint function values is still bounded by the absolute constraint value at the nominal parameter value $\mathbf{p}_0$.

$$\begin{aligned} \eta_g \leq 1 \quad \text{where } \eta_g &= \begin{cases} \max_{\mathbf{p}, j} \frac{g_j(\mathbf{x}_0, \mathbf{p}) - g_j(\mathbf{x}_0, \mathbf{p}_0)}{|g_j(\mathbf{x}_0, \mathbf{p}_0)|}, \\ \quad \text{if } g_j(\mathbf{x}_0, \mathbf{p}) \geq g_j(\mathbf{x}_0, \mathbf{p}_0) \\ 0, \quad \text{otherwise} \end{cases} \\ & \text{s.t. } \mathbf{p}_0 - \Delta\mathbf{p} \leq \mathbf{p} \leq \mathbf{p}_0 + \Delta\mathbf{p}, j = 1, \dots, J \end{aligned} \quad (13)$$

After the treatment of the uncertainty using above strategies, the robust optimization problem can be solved through the optimization methods suitable for the deterministic case.

Definition

Ships are built on land and sail on rivers or oceans, so the main steel hull and numerous outfitting pieces will be corroded by the industrial atmosphere and the marine environment. Corrosion can cause great damage to ships and reduce the strength of ship structures (Xu 2005). When the steel ship is corroded to a certain degree, the strength of the hull will be reduced to be insufficient to withstand the huge impact of the ocean wind and waves on the hull, and a shipwreck is inevitable. When the various equipment of the ship is corroded to a certain degree, the equipment cannot work and operate normally, which will cause various accidents. In severe cases, the ship will lose control and its self-rescue ability in the ocean, causing disasters finally. Therefore, when the ship is corroded to a certain degree, it has to be scrapped and lose its use-value.

The corrosion of steel ships in the ocean is inevitable, but the rate of corrosion can be controlled. In order to prevent the corrosion of steel and prolong the service life of ships, steel, hulls, outfitting steel structural pieces, pipe system, and

cabinet must be rust removal and painted. This kind of surface treatment is called ship painting. In addition to anti-corrosion effects, ship painting also has the effects of exterior decoration and anti-foul (Liu et al. 2011).

Introduction

Operation Method of Ship Painting

The ship painting method is coordinated with the block construction method of the hull construction and the regional outfitting method of ship outfitting. Therefore, ship painting operations include steel pretreatment, sectional painting, shipboard painting, and finished coat, as shown in the following figure. Among them, the painting of outfitting pieces, the painting of the brackets, bases, strong back, and other outfitting pieces connected with the hull belong to the scope of sectional painting; the painting of other outfitting units and outfitting pieces should be completed at the later stage of unit outfitting and outfitting pieces production, so they are all in-site operations (Fig. 1).

Steel Pretreatment

Steel pretreatment is the leveling, rust removal (including oxide scale), and protective paint on the steel. The process method and process of steel pretreatment have been discussed in detail above, and the automatic assembly line of steel

Painting Technology, Fig. 1 Painting stage and process

pretreatment has been briefly introduced, so there is no need to repeat it here (Li et al. 2006).

Sectional Painting

After the steel pretreatment is made into sections by component processing and structural pre-assembly welding, the surface of the steel structure will inevitably produce zinc salt, rust, oil stains, moisture, etc., so a second rust removal is required, and then spray primer according to the different requirements of the sections. The secondary rust removal and primer spraying operations for the sections are called sectional painting. In order to control the environmental conditions of the painting operation and ensure the quality of the painting, indoor operations should be used for sectional painting, so the second stage of rust removal is best to use shot blasting in the shot blasting room. It uses the pressure of high-speed flowing compressed air in the air duct to make iron shots impact the rust spots on the metal surface to achieve rust removal. In addition to the iron shot blasting device, the shot blasting room is also equipped with rails and section loading vehicles, iron shot recovery devices and rust dust suction devices to ensure shot blasting operating conditions, and rust removal quality. Outside the house is equipped with sectional dispatching equipment and indoor workplaces for sectional spray primer. The primer should be sprayed immediately after rust removal in sections,

otherwise yellow rust will easily occur and affect the quality of rust removal. Sometimes due to various conditions, it is necessary to carry out sectional painting operations on the field platform. At this time, most of the sectional rust removal uses pneumatic tools, such as pneumatic grinder, pneumatic control wire brushes, etc.; primer spraying uses portable airless spraying equipment (Wang et al. 2019).

Shipboard Painting

The painting work on the berth (in the dock) before launching the ship and at the dockside after launching is called shipboard painting. The painting operations onboard include rust removal, cleaning, touch-up painting, and spraying of the inner and top coats on various parts of the outer surface of the hull. If there is no subsequent outfitting work for the oil tanks, water tanks, and other liquid tanks inside the hull, painting operations can be completed on the hull (in the dock). However, due to the busy outfitting operation in the ship, the hull deck is easy to wear and tear the paint film and is left to be painted at the later stage of outfitting at the wharf (He et al. 2020).

Finished Painting

The painting operation before delivery is called finished painting. Finished painting is generally completed within a period of time from the end of the trial voyage to the delivery of the ship, so that

when that ship is hand over to the owner, it will look quite new. However, as long as the ship-owner agrees, the finished painting operation can also be carried out in advance. Finished painting operations include the cleaning and touch-up of the outer surface of the superstructure, deck, and deck machinery, as well as the spraying of the last topcoat on the outer surface of the hull; organic solvents are used to clean up grease and other stains before the paint is repaired. The last coat of paint on each part of the outer surface of the main hull is usually sprayed in the dock. Firstly, the bottom of the ship is washed with clean water to remove salt and soil. Secondly, the paint is repaired after drying (e.g., the first paint film is often damaged by the anchoring test). Thirdly, the finish coat is sprayed.

Common Paint for Ships

Paint is usually composed of binders, pigments, diluents, and additives. Among them, the binder is the main film-forming substance; the pigment is the secondary film-forming substance, which can color the paint film and improve the performance of the paint film; the diluent, a volatile substance is used to dissolve and dilute the paint for operation; the additive is used to make the paint film have specific properties, such as antifouling, corrosion inhibition, and plasticization. Paint can be classified according to binders. The commonly used binders are natural resin, mineral asphalt, and synthetic resin. Synthetic resin is widely used in modern marine paint, mainly including alkyd resin, ethylene resin, epoxy resin, chlorinated rubber, polyurethane resin, and inorganic zinc paint.

Cathodic Protection of the Hull

It is not enough for ships to rely on paint to prevent corrosion. For example, exposed copper propellers in water and contact with steel structures such as propeller shafts and stern posts exposed in the water will produce battery effects and cause corrosion of the steel components at the

tail. Another example is that the poor paint film of the bottom of the ship at the keel block, insufficient thickness of paint film at the weld seam of the outer plate, and local paint film scratches on the side outer plate will cause electrochemical corrosion in the marine environment (Cho et al. 2016). In order to make up for the deficiencies of anti-corrosion treatment, cathodic protection is generally used as an auxiliary means of anti-corrosion for the hull. According to the electrochemical principle, the metal with lower electroplating potential will be used as the anode in the corrosion battery to release electrons, thus causing it to be corroded. Cathodic protection is to polarize the protected metal as a cathode so that it can capture electrons and be protected. According to different polarization principles, there are two kinds of cathodic protection: sacrificial anode method and impressed current method.

Parametrically excited roll

Definition

Parametric rolling is a dynamic stability phenomenon in which an amplification of roll motion is caused by periodic variation of transverse stability

in waves. The phenomenon of parametric rolling is predominantly observed in head, following, bow, and stern-quartering seas when the ship's encounter frequency is approximately twice that of the ship's roll natural frequency and the ship's roll damping is insufficient to dissipate additional energy (SDC 3/WP.5/Annex 4,2016).

Figures 1 and 2 shows the process by which parametric rolling develops. If the ship rolls while in the wave trough, increased stability provides stronger pushback, or restoring moment. As the ship returns to the upright position, its roll motion rate is increased, since there was an additional pushback from the increased stability. At that time, however, the ship will roll further to the opposite side because of the greater roll motion rate and less resistance to heeling. Then, if the wave trough reaches the midship section when the ship reaches its maximum amplitude roll, stability increases again and the cycle starts again.

Parametric Rolling, Fig. 1 Development of parametric roll resonance (Belenky et al. 2011; SDC 3/WP.5/Annex 4,2016)

Parametric Rolling, Fig. 2 Time histories plots of parametric roll resonance (SDC 3/WP.5/Annex 4,2016)

There are two waves that pass during each roll period (SDC 3/WP.5/Annex 4,2016).

Scientific Fundamentals

The roll motion in head or following seas can be expressed as follows:

$$\begin{aligned} & (I_{xx} + A_{44})\ddot{\varphi} + N_1\dot{\varphi} + W \\ & \cdot GM\left(1 + \frac{\Delta GM}{GM} \cos \omega_e t\right) \varphi \\ & = 0 \end{aligned} \quad (1)$$

where φ : roll angle, N_1 : linear roll damping coefficient, W : ship weight, I_{xx} : moment of inertia in roll, A_{44} : added moment of inertia in roll, GM : metacentric height in calm water, ΔGM : the variation of metacentric height in waves, ω_e : encounter wave frequency, and t : time. The dot denotes the differentiation with time.

The roll equation (1) can be rewritten as follows:

$$\ddot{\varphi} + 2\mu\dot{\varphi} + \omega_0^2\left(1 + \frac{\Delta GM}{GM} \cos \omega_e t\right) \varphi = 0 \quad (2)$$

where $2\mu = \frac{N_1}{I_{xx} + A_{44}}$, $\omega_0 = \sqrt{\frac{W \cdot GM}{I_{xx} + A_{44}}}$, ω_0 : natural roll frequency.

The roll equation (2) can be further rewritten as follows:

$$\ddot{\varphi} + 2\mu^*\dot{\varphi} + (\delta + 2\varepsilon \cos 2\tau)\varphi = 0 \quad (3)$$

where $\mu^* = \frac{2\mu}{\omega_e}$, $\delta = 4\frac{\omega_0^2}{\omega_e^2}$, $2\varepsilon = 4\frac{\omega_0^2}{\omega_e^2} \frac{\Delta GM}{GM}$, $\tau = \omega_e t/2$.

If the damping coefficient is ignored, the standard Mathieu equation can be obtained as follows:

$$\ddot{\varphi} + (\delta + 2\varepsilon \cos 2\tau)\varphi = 0 \quad (4)$$

The solution of the standard Mathieu equation is as follows, and the stability diagram of the Mathieu equation is shown in Fig. 3.

$$\begin{aligned} \delta_0 &= -\frac{1}{2}\varepsilon^2 + O(\varepsilon^3), \\ \delta_1 &= 1 - \varepsilon - \frac{1}{8}\varepsilon^2 + O(\varepsilon^3), \delta'_1 = 1 + \varepsilon - \frac{1}{8}\varepsilon^2 + O(\varepsilon^3) \\ \delta_2 &= 4 - \frac{1}{12}\varepsilon^2 + O(\varepsilon^3), \delta'_2 = 4 + \frac{5}{12}\varepsilon^2 + O(\varepsilon^3) \end{aligned} \quad (5)$$

From the stability diagram, we see that unstable motion can occur at several different ratios of ω_e/ω_0 . The shadow area means unstable region. The predominant value of this ratio is $\delta = 4\omega_0^2/\omega_e^2 = 1$, meaning that oscillation at the natural frequency occurs if the frequency of encounter is twice the natural frequency. This instability phenomenon is an example of a dynamic motion “bifurcation.” A small initial disturbance $2\varepsilon = \Delta GM/GM$ can trigger a growing oscillation, meaning that a small variation of GM in waves could trigger a growing roll motion, even capsizing in this unstable region. The unstable region becomes large as ΔGM increases. This phenomenon is called parametric rolling.

Parametric Rolling,**Fig. 3** Stability diagram of the Mathieu equation**Parametric Rolling,****Fig. 4** Stability diagram of the Mathieu equation for parametric rolling

The basic value of this ratio is $\delta = 4\omega_0^2/\omega_e^2 = 4$, meaning that oscillation at the natural frequency occurs if the frequency of encounter equals the natural frequency. This instability phenomenon is not discussed here.

If roll damping is considered as shown in Eq. (3), the solution of the Mathieu equation for parametric rolling is as follows, and the stability diagram of the Mathieu equation for parametric rolling is shown in Fig. 4.

$$\delta - 1 = -\frac{1}{8}\epsilon^2 \pm \sqrt{\epsilon^2 - (2\mu^*)^2} \quad (6)$$

The shadow area means an unstable region, and there is a threshold value $\epsilon = 2\mu^*$ for unstable region. If $2\mu^* \geq \epsilon$, it is stable. If $2\mu^* < \epsilon$, it is unstable, meaning that if $4\mu^* < \frac{\Delta GM}{GM}$ and $\omega_0/\omega = 1/2$, parametric rolling could occur.

Typical Parametric Rolling Accident

In late October 1998, a C11 class, post-Panamax containership, which is 262 m LBP, and 24.45m Depth with a loaded draft of about 12.5m, east-bound in the north Pacific from Kaohsiung to

Seattle, was overtaken by a severe storm. She carried a deck stow of some 1300 containers. As encounter with the storm became inevitable, the master rode out hove to the rough seas and winds. The storm encounter lasted for some 11 hours, mostly at night. During the period of severest motions, port and starboard rolling of as much as 35–40 degrees was reported simultaneously with extreme pitching. The master later described the ship as absolutely out of control. About 400 containers were lost overboard, and another 400 collapsed or crushed during these motions (SLF45/6/7,2002) (Fig. 5).

In February 2003, the Wallenius PCTC M/V Aida experienced sudden violent rolling in rough head seas southwest of the Azores. Roll angles as large as 50 degrees were read off the bridge inclinometer. When this incident was postanalyzed, it was found that the condition, in terms of the relation of wave encounter period and natural roll period, was such that parametric rolling was most likely the case. Partly due to this accident, M/V Aida was equipped with a Seaware EnRoute Live system in December 2003 for trial during the winter. In February 2004, on a voyage from Southampton to New York, Aida encountered heading sea with significant wave height 5–6 m and traveled with reduced speed 8–10 knots west

Parametric Rolling,

Fig. 5 APL China containership suffered parametric rolling (<http://marineinbox.com/marine-exams/parametric-rolling-in-container-ships/>)

of the Azores. At five different occasions, parametric rolling evolved, with roll angles up to 17 degrees. The strong pitch-roll coupling during head-sea-parametric rolling is clearly demonstrated by the recorded motion time series with the Seaware EnRoute Live system (SLF47/INF.5 2004).

Historical Development

Before the accident of the C11 class containership, parametric rolling is mainly dealt with in the cases of following waves (Kerwin 1955) or beam waves (Blocki 1980). In particular, clear experimental records of capsizing due to parametric rolling in following waves were published by Umeda (Umeda et al. 1995). In case of following waves, the encounter frequency is much lower than the natural frequencies of heave and pitch so that coupling with heave and pitch is not important. In addition, added resistance in following waves is generally small. Thus, several successful predictions of parametric rolling in following waves were reported (Munif and Umeda 2000). In case of head waves, however, prediction of parametric rolling is not so easy because coupling with heave and pitch is significant and added resistance cannot be ignored. The effect of dynamic heave and pitch motions on parametric rolling was investigated so far by many researchers and is well established: Restoring

arm variation in head waves depends on dynamic heave and pitch (Taguchi et al. 2006). On the other hand, effect of added resistance on parametric rolling seems to require further investigation. Jensen (Jensen et al. 2007) discussed the effect of surge motion on the probability of parametric rolling in irregular head waves, but their surge model does not include added resistance. Umeda (Umeda et al. 2008) and Umeda and Francescutto (Umeda et al. 2008) executed numerical simulation of parametric rolling in regular and irregular head waves with added resistance taken into account, but their hydrodynamic prediction method for added resistance is different from that for restoring variation. Lu et al. (2011) further developed a numerical prediction method for parametric roll in head waves in which both the restoring variation and the Kochin function for added resistance are calculated with a strip theory.

Key Numerical Method for Parametric Rolling

It is widely accepted that degrees of freedom (DOF) of a rigid body in a three-dimensional space are six but can be reduced if constraints are added. First of all, because of head waves, we can assume that a ship runs with the constant course so that there is no sway and yaw motions are two constraints so that the degrees of freedom become four. Then if the heave and pitch motions

are assumed to be independent from the surge and roll motions, the heave and pitch motions themselves can be regarded as two constraints so that the degrees of freedom become two. Further, if we assume that the ship runs with a constant speed, the degrees of freedom become finally one.

A coupled heave-roll-pitch-mathematical model which is based on a nonlinear strip theory called 3 DOF approach is widely used for predicting parametric rolling. The mathematical model is expressed as (7), (8), and (9).

$$\begin{aligned}
 (m + A_{33}(\varphi))\ddot{\zeta} + B_{33}\dot{\zeta} + A_{34}(\varphi)\ddot{\varphi} \\
 + B_{34}(\varphi)\dot{\varphi} \\
 + A_{35}(\varphi)\ddot{\theta} \\
 + B_{35}(\varphi)\dot{\theta} \\
 = F_3^{FK+B}(\xi_G/\lambda, \zeta, \varphi, \theta) \\
 + F_3^{DF}(\varphi)
 \end{aligned} \quad (7)$$

$$\begin{aligned}
 (I_{xx} + A_{44}(\varphi))\ddot{\varphi} + N_1\dot{\varphi} + N_3\dot{\varphi}^3 + A_{43}(\varphi)\ddot{\zeta} \\
 + B_{43}(\varphi)\dot{\zeta} + A_{45}(\varphi)\ddot{\theta} + B_{45}(\varphi)\dot{\theta} \\
 = F_4^{FK+B}(\xi_G/\lambda, \zeta, \varphi, \theta) + F_4^{DF}(\varphi)
 \end{aligned} \quad (8)$$

$$\begin{aligned}
 (I_{yy} + A_{55}(\varphi))\ddot{\theta} + B_{55}(\varphi)\dot{\theta} \\
 + A_{53}(\varphi)\ddot{\zeta} + B_{53}(\varphi)\dot{\zeta} + A_{54}(\varphi)\ddot{\varphi} \\
 + B_{54}(\varphi)\dot{\varphi} \\
 = F_5^{FK+B}(\xi_G/\lambda, \zeta, \varphi, \theta) + F_5^{DF}(\varphi)
 \end{aligned} \quad (9)$$

A_{ij} , B_{ij} , and C_{ij} are the coupling coefficients in

seakeeping theory. Nonlinear Froude-Krylov forces (FK) and hydrostatic force (B) are calculated by integrating the incident wave pressure around the instantaneous wetted hull surface by two-dimensional strip method or three-dimensional panel method. Radiation and diffraction forces are calculated for the submerged hull considering time-dependent roll angle with the static balance retained in sinkage and trim by two-dimensional strip method or three-dimensional panel method. The hydrodynamic forces in heave and pitch are calculated at the encounter frequency while those for roll mode are calculated at half the encounter frequency assuming parametric roll occurs. The linear and cubic roll-damping coefficients are used in the mathematic model which are obtained from the roll decay test in the experiment or Ikeda's method. The model used here also includes the body-nonlinear hydrodynamic coupling between roll and vertical motions, and the nonlinearity of vertical motions is ignored.

Equation (8) can be rewritten as below if one only considers Froude-Krylov components in the roll-restoring variation.

$$\begin{aligned}
 (I_{xx} + A_{44}(\varphi))\ddot{\varphi} + N_1\dot{\varphi} + N_3\dot{\varphi}^3 \\
 = F_4^{FK+B}(\xi_G/\lambda, \zeta, \varphi, \theta)
 \end{aligned} \quad (10)$$

The 3 DOF approach can also be simplified to 1 DOF approach if the heave and pitch motions are obtained by a strip theory applied to an upright hull.

$$\begin{aligned}
 \ddot{\varphi} + 2\mu\dot{\varphi} + \gamma\varphi^3 + \frac{W}{I_{xx} + A_{44}}GZ_{FK+R\&D}(t, X_G, \zeta_G, \theta, \varphi) = 0 \\
 GZ_{FK} = \frac{-F_4^{FK+B}(\xi_G/\lambda, \zeta, \varphi, \theta)}{W} \\
 GZ_{R\&D} = \frac{-F_4^{DF}(\varphi) + \left(A_{43}(\varphi)\ddot{\zeta} + B_{43}(\varphi)\dot{\zeta} + A_{45}(\varphi)\ddot{\theta} + B_{45}(\varphi)\dot{\theta} \right)}{W}
 \end{aligned} \quad (11)$$

FK: Only Froude-Krylov and hydrostatic components in roll direction are considered.

FK+R&D: The radiation and diffraction components in roll direction are also considered.

If the time-varied speed due to the surge motion is considered in 1 DOF approach, 2 DOF numerical approaches can be realized. If the time-varied speed due to the surge motion is considered in 1 DOF approach, 4 DOF numerical approaches can be realized. The time-varied speed due to the surge motion can be shown as follows.

$$\begin{aligned} (m + A_{11}) \ddot{X}_G &= \left(T \dot{X}_G, n \right) - R \left(\dot{X}_G \right) \\ &+ F_1^{FK} (X_G, t) \\ &- R_{AW} \left(\overline{X}_G, t \right) \end{aligned} \quad (12)$$

$$T(X_G, n) = (1 - t_p) \rho n^2 D_p^4 K_T \left\{ \frac{X_G (1 - w_p)}{n D_p} \right\} \quad (13)$$

$$\overline{X}_G = \frac{1}{T_e} \int_0^{T_e} \dot{X}_G(t) dt \quad (14)$$

where φ : roll angle, μ : linear roll-damping coefficient, γ : cubic roll-damping coefficient, W : ship weight, I_{xx} : moment of inertia in roll, A_{44} : added moment of inertia in roll, I_{yy} : moment of inertia in pitch, A_{55} : added moment of inertia in pitch, GZ : righting arm, t : time, ζ_G : heave displacement and θ : pitch angle, and X_G : instantaneous ship-longitudinal position. The dot denotes the differentiation with time.

Furthermore, T : propeller thrust, R : ship resistance in calm water, and R_{AW} : added resistance in waves.

Experimental Method for Parametric Rolling

Free Running Experiment Method

The ship model was driven by a propeller in regular head seas in the free running experiment. The pitch and roll amplitudes were measured by a MEMS (Microelectromechanical system)-based gyroscope placed on the ship model, and the

wave elevation was measured by a servo-needle wave height sensor attached to the towing carriage.

Partially Restrained Experiment

A multifunctional equipment was used in the partially restrained experiment. The equipment as shown in Fig. 6 consists of five components. The first component is a pedestal and four locking jaws for fixing the equipment to the towing carriage. The second component is a mechanism for keeping the ship model free in heave and measuring the displacement of heave motion and consists of a guide rail bracket, a linear guide rail pair, a displacement sensor using a guide wire, a heave rod, a block, and so on. The third component is three diverging combined sensors using rods for measuring the surge force, the sway force, and the yaw moment in which a strain gauge-measuring technique is applied. The fourth component is a complex movement mechanism for measuring

Parametric Rolling, Fig. 6 The new equipment for restrained experiment

pitch, roll motions with potentiometers, and roll moment with a double flange torque sensor by fixing a certain roll angle with a locking mechanism. The fourth component is fixed to the ship model, and its weight is regarded as one part of the ship model. The third component is fixed with the fourth component, and the second component is fixed with the third component, and their weights are not part of the ship model for the convenience of arranging and adjusting the center of gravity and moments of inertia. The fifth component is a mechanism for balancing the weight of the second component and third component and consists of a pulley block, a vertical guide rod, a counter-weight, and so on.

Surge, sway, and yaw motions are always restrained; heave and pitch motions are always free, and roll motion can be free or restrained by the equipment in partially restrained experiments. Therefore, parametric roll, pitch, and displacement of heave can be measured simultaneously. When roll is fixed with a certain angle, the roll moment and the sway force can be measured simultaneously by this equipment, and then the restoring moment can be calculated by roll moment, sway force, and vertical distance between the double flange torque sensor of the equipment and the center of gravity of the ship model.

The principal particulars and body plan of the C11 class containership are shown in Table 1 and Fig. 7, respectively. The ship models the free running experiment and partially restrained experiment are shown Figs. 8 and 9, respectively.

Parametric Rolling, Table 1 Principal particulars of the C11 containership

Items	Ship	Model
Length: L	262.0m	4.000m
Draft: T	11.5m	0.176m
Breadth: B	40.0m	0.611m
Depth: D	24.45m	0.373m
Displ.: W	67508 ton	240.2kg
C_B	0.560	0.560
GM	1.928m	0.029m
T_ϕ	24.68s	3.05s
K_{YY}	0.24L	0.24L

The Effect of the Surge Motion on Parametric Rolling

The uncoupled roll model (1 DOF) and the coupled surge-roll model (2 DOF) with added resistance taken into account are used to numerically investigate the effect of surge motion on parametric roll. An example of time series is shown in Fig. 10. Free running model experiments, which allow the surge motion and partially

Parametric Rolling, Fig. 7 Lines of C11 containership

Parametric Rolling, Fig. 9 The ship model in partially restrained experiment

Parametric Rolling, Fig. 10 Comparisons between time series with surge motion and without surge motion, under the condition of the actual $F_n=0.05$, $\lambda/L_{pp}=1.0$,

$H/\lambda=0.01$, and $\chi=180^\circ$. (1DOF(FK+R&D) and 2DOF (FK+R&D) approaches)

restrained model experiments without surge motion, were also conducted to investigate the effect of surge motion on parametric roll. More comprehensive comparisons are shown in Figs. 11 and 12.

The simulations indicate that the effect of the surge motion on parametric rolling is generally small in regular head seas. This is because the difference of the longitudinal ship position is

rather small between the calculations with and without surge motion; consequently, the difference between the relative wave profile around the ship and the change of GZ are very small too, although the ship's forward speed varies periodically due to the surge motion in regular head seas. This conclusion can be applied to the modeling of the roll-restoring variation with and without the radiation and the diffraction components.

Parametric Rolling, Fig. 11 The effect of surge motion on parametric roll as function of Froude number in experiments and simulations with $\lambda/L_{pp}=1.0$, $\chi=180^\circ$ (FK: Only Froude-Krylov components in roll direction are considered)

Parametric Rolling, Fig. 12 The effect of surge motion on parametric roll as function of Froude number in experiments and simulations with $\lambda/L_{pp}=1.0$, $\chi=180^\circ$ (FK+R&D: The radiation and diffraction components in roll direction are also considered)

The Effect of Parametric Rolling on Heave and Pitch Motions

The effect of dynamic heave and pitch motions on parametric rolling was investigated so far by many researchers, and it is well established that restoring arm variation in head waves depends on dynamic heave and pitch motions. Coupling from heave, pitch to parametric roll is usually considered, but the effect of parametric roll on heave and pitch motions is ignored. Partially restrained model experiments free in heave and pitch but with a constant roll angle were conducted, and then, partially restrained model experiments free in heave, pitch, and roll for simultaneously measuring parametric roll, pitch, and heave were conducted, and the results are shown in Figs. 13 and 14. The spectra of the ship motions by the Fourier transformation are also shown in Figs. 13 and 14.

The results from the experiments indicate the frequency of heave and pitch motions is equal to the encounter wave frequency in the case without parametric roll as shown in Fig. 13, which is consistent with a linear seakeeping theory. When

parametric roll occurs with the amplitudes of about 10 degrees as shown in Fig. 14, heave and pitch motions are affected by parametric roll: Their large and small amplitudes alternately appear. This phenomenon seems like “subharmonic pitch” and “subharmonic heave.” The heave and pitch motions are analyzed in the frequency domain by the Fourier transformation. One distinct observation was that pitch and heave motions in the experiments have both half the encountered wave frequency and the encountered wave frequency components when parametric roll occurs.

The Effect of Dynamic Roll Variation on Parametric Rolling

Parametric rolling in head seas is a nonlinear phenomenon due to roll-restoring force variation. The calculated roll motions with the 1 DOF approach and the 3 DOF approach are shown in Figs. 15 and 16 together with the results of free running model. The calculations of the roll-restoring variation are performed with and

Parametric Rolling, Fig. 13 Pitch and heave motions under the constant roll angle in the partially restrained experiment with $\lambda/L_{pp}=1.0$, $H/\lambda=0.01$, $\chi=180^\circ$, and $F_n=0.0$

Parametric Rolling, Fig. 14 Roll pitch and heave motions in the partially restrained experiment allowing the roll motions with $\lambda/L_{pp}=1.0$, $H/\lambda=0.01$, $\chi=180^\circ$, and $Fn=0.0$

without the radiation and diffraction components as shown in Figs. 17 and 18.

The prediction of parametric rolling in the 1 DOF approach and 3 DOF approach with Froude-Krylov, radiation, and diffraction components is generally larger than that in the experiments while the prediction of parametric roll with the Froude-Krylov on its own is generally smaller than that in the experiments except for $H/\lambda=0.01$ as shown in Figs. 15 and 16. The prediction of parametric roll with the 1 DOF approach is generally larger than that with the 3 DOF approach as shown in Figs. 15 and 16, while the prediction with the 3 DOF (FK+R&D) approach is closer to

the results in experiments than that with the 1 DOF (FK+R&D) approach.

Key Applications

Parametric rolling is one of the five stability failure modes in the second-generation intact stability criteria which include Level 1 and Level 2 vulnerability criteria and direct stability assessment. The main purpose of these criteria is to enable the use of the latest numerical simulation techniques for evaluating the safety level of a ship from an intact stability viewpoint (IMO, Msc.1/Circ.1627 2020).

Parametric Rolling, Fig. 15 Comparisons of parametric roll as function of Froude number in experiments, 1 DOF approach and 3 DOF approach with $\lambda/L_{pp}=1.0$, $\chi=180^\circ$

Parametric Rolling, Fig. 16 Comparisons of parametric roll as function of Froude number in experiments, 1 DOF approach and 3 DOF approach with $\lambda/L_{pp}=1.0$, $\chi=180^\circ$

Parametric Rolling,

Fig. 17 Comparisons of roll-restoring variation in experiments and simulations with $\lambda/L_{pp}=1.0$, $H/\lambda=0.02$, $\chi=180^\circ$, and heeling angle 7.3 degrees

Parametric Rolling,

Fig. 18 Comparisons of roll-restoring variation in experiments and simulations with $\lambda/L_{pp}=1.0$, $H/\lambda=0.01$, $\chi=180^\circ$, and heeling angle 7.3 degrees

Parametric rolling is a complicated phenomenon when the ship is sailing in the seas, and the direct stability assessment is related to complex hydrodynamics. The above introduction on parametric rolling could be useful for shipbuilders, shipmasters, shipowners, ship operators, and shipping companies to understand parametric rolling.

Definition

Underwater photoelectric detection technology is used for target detecting and imaging in the environment of underwater, using electro-optic detection method. Compared with acoustic detection techniques, photoelectric detection has the advantages of high resolution ratio, no near-field blind area, and fast and convenient for target identification. At present, the underwater photoelectric detection methods include range-gated imaging detection, laser line scanning imaging detection, polarization imaging detection, modulation/demodulation imaging detection, structured light imaging detection, etc. (Cao et al. 2011).

Scientific Fundamentals

Compared with land photoelectric imaging system, underwater photoelectric imaging and detection system work in special environment. There are mainly three parts in underwater photoelectric imaging and detection system, including underwater lighting system, underwater imaging lens, and detector (Yuan 2013).

Figure 1 shows the working principle. In Fig. 1, laser light source lights the underwater target, and the light reflected by the target enters the optical sensor through the aquatic medium and absorbed scattered by the water at the same time.

Photoelectric Detection Technology in Underwater Vehicles, Fig. 1 Underwater photoelectric imaging and detection system working principle

There are target light, scattering light and back-light showing on the image plane. Target image focuses on the plane of the optical sensor. The photoelectric device takes target image and sends it to the recording device after signal processing. The optical sensor's imaging quality can be affected by the absorption and scattering of light from the water.

Difficulties of Underwater Photoelectric Detection

Since 1963, S.Q. Duntley et al. found that the attenuation of blue and green light in 0.45 μm –0.55 μm band by sea water is much smaller than that in other bands (Zhao et al. 2014). The detection of underwater targets and environments such as oceans and lakes by laser irradiation has attracted more and more attention in the world and has also opened up a new way of underwater target detection. Due to the particularity of underwater environment, the key problems of underwater target detection are two aspects: one is how to suppress the backscattering effect of suspended particles in water and improve the imaging contrast; the other is how to overcome the attenuation effect of water on laser energy.

Attenuation Characteristics of Light in Water

Underwater working system and terrestrial imaging system are different, mainly because of the influence of water on the characteristics of light. The absorption and scattering of water to light are the main factors affecting the quality of underwater imaging. The attenuation characteristic of light in water refers to that the energy of light decreases exponentially in the course of transmission due to the absorption and scattering of water, which limits the propagation distance of light in water. And the scattering of water to light will result in the low contrast of the underwater image. If the light is only affected by the absorption of water in the process of transmission, then the absorption of water can be overcome by increasing the power of the light source. Thus, the imaging distance can be increased. However, due to the existence of scattering, increasing the power of the light source,

the power of the target-reflected light and scattered light are increasing at the same time. Then the image contrast obtained by the photoelectric receiver will not be improved. So simply increasing the power of the light source cannot improve the underwater imaging distance. It has been found that the underwater imaging distance is generally about more than 10 m, which is an urgent problem for the underwater optical imaging system, and also the main reason for the application limitation of the underwater optical imaging system.

Absorption of Light by Water

The absorption selectivity of water to light is obvious. The absorption rate of water is different in different spectral regions. The absorption of water to ultraviolet and infrared bands is stronger, but the absorption to blue-green bands is weaker. In the visible region, absorption of water is the largest in red, yellow, and light-green spectral regions. So color distortion will occur after transmitting light a certain distance underwater. When the underwater imaging distance is relatively long, the image is usually gray. In the water with low turbidity, the absorption in the blue-green band is the smallest, which is the so-called "blue-green window" of underwater imaging. But even in this blue-green window, the underwater transmission of light is greatly affected by the absorption of water. After a 1-m underwater transmission, the attenuation of light intensity reaches at least 4%. In other spectral regions, light is almost completely absorbed several meters away. So even in the blue-green window, the absorption of water will make the imaging distance very limited. Therefore, the influence of water absorption characteristics on the underwater imaging system must be fully considered in the research and analysis of the operating range of the underwater imaging system (Chen et al. 2011).

Light Scattering Characteristics of Water

Light scattering by water means that when light propagates in water, the direction of light propagation will change due to the action of various medium particles in water. The scattering of sea water is more complex than that of the

atmosphere. There are mainly two types of scattering: the scattering caused by pure water and the scattering caused by suspended particles. These include Rayleigh scattering, Mie scattering and the scattering caused by the refraction of transparent materials. The scattering functions of different sea areas and different water types are quite distinguished. Clean sea water is mainly scattered by water molecules, while turbid water along the coast is mainly scattered by large particles. The scattering mode can be divided into forward scattering and backward scattering according to the direction of scattered light. The scattering of water and particles to light is mainly forward scattering, which generally accounts for more than 90% of the total scattering, while backscattering only accounts for a small part. Forward scattering and backward scattering will affect the quality of the underwater imaging image. Although backscattering accounts for a small proportion, in underwater laser imaging applications backscattering affects image contrast and is the main factor affecting image quality.

Underwater Photoelectric Detection Technology

Range-Gated Imaging Detection Technology

Instead of using continuous laser, range gating technology uses the pulsed laser to emit the laser light and illuminate the target. The receiving end uses range-gated selection. When the target light reaches the receiver, the gate opens, so that the receiver receives the reflected light from all the scenery in the whole field of view. Before that the gating door has closed, thus eliminating the arrival of the background light during other periods. Its working principle is shown in Fig. 2.

The laser illuminates the target actively and then is reflected by the target. Before the light wave reaches the detection receiver, the gate is always in a "closed" state. Only within the very short time when the reflected light of the target reaches the receiver, the gate opens, and the reflected light enters the receiver for imaging. Thus, the target light and scattered light are separated from each other in time, and most of the forward and

Photoelectric Detection Technology in Underwater Vehicles,

Fig. 2 Principle diagram of range-gating synchronization control technology (Jin et al. 2011)

backward scattered light of the laser is eliminated from the optical receiver. And this reduces the background noise formed by the scattered light on the detector and improves the signal-to-noise ratio and contrast of the target image.

The laser underwater imaging system, which employs range-gated technology, uses the pulsed laser as the light source. In the process of light transmission underwater, the gate in front of the optical receiver is always closed and only opens at the time when the target-reflected light reaches the detector. At this moment, the receiver receives the reflected light from all the scenes in the whole field of view, including scattered light, target-reflected light, background light, etc. Therefore, the range-gated underwater laser imaging system can eliminate most of the backscattered light, but it cannot be completely eliminated. Moreover, the observation field of the laser underwater imaging system using range-gated technology is narrow. To improve the underwater imaging distance and make the laser irradiate the whole field of view at the same time, the high-energy laser pulse is used to focus on a relatively small area, so that the image observed under the condition of narrow field of view will be clear.

The performance of the range-gated imaging system depends on the gated pulse width and laser pulse width. If both are very narrow, only the light near the target can enter the receiver and the

scattered light and background light will be suppressed. This is conducive to the improvement of imaging quality.

Laser Line Scanning Imaging Detection Technology

Synchronized scanning technology is to synchronize the scanning beam and the receiving line of sight. The imaging technology utilizes the principle that the backscattered light intensity of water decreases rapidly relative to the central axis. It can suppress the backscattered light from space into the receiver, thus overcoming the influence of backscattered light and improving the imaging quality. The image shown in Fig. 3 is a typical optical path diagram of the system.

The scanning light and the receiving line of sight are synchronized. The laser and receiver are separated in space. The laser emits continuous narrow beams, and the receiver uses narrow field of view. There is only a small overlap between the two fields of view. The overlap area between illuminated water and receiver is minimized to reduce the scattered light entering the receiver and does not affect the target-reflected light entering the receiver. This effectively reduces the background noise without reducing the reflected light energy, thus effectively improving the imaging distance and image quality. Using synchronous scanning technology, point-by-point detection is

Photoelectric Detection Technology in Underwater Vehicles, Fig. 3 Principle of laser synchronous scanning imaging

used to form images. This method can scan a wide area up to 120° , and the effective field of view can reach 70° . The key to the image quality of synchronous scanning imaging technology lies in the tracking and receiving of highly sensitive detectors in the small field of view. The key to the realization of synchronous scanning technology lies in the synchronous control of the scanning beam and receiving the line of sight. The synchronous control methods are divided into mechanical synchronization and signal synchronization. Mechanical synchronization is used often.

Principle of Polarization Imaging Detection

Each object has a depolarization effect. The depolarization degree of sea water and object to light is different. If polarized light is used to irradiate underwater objects near Lambertine, the approximate depolarization of the object can be obtained according to the scattering theory. According to the knowledge of scattering, different objects have different scattering rates to the same light source. For objects approximate Lambertine, the scattering rate is generally less than that of backscattering light of particles in water. The depolarization of reflected light of objects is different from that of scattering light of particles in water. Therefore, according to the difference of depolarization between the backscattering light of particles and the object reflecting light in sea water, the backscattered light of particles can be suppressed by adjusting the angle of the polarizer in front of

the receiver, and the reflecting light of the object passes through the analyzer to enter the imaging system. Although the energy of backscattered light and target-reflected light are reduced by polarization technology, the degree of their reduction is different, and the backscattered light is reduced more, so the contrast of the image can be improved. There are two kinds of polarization technology: circular polarization technology and linear polarization technology. Both circular polarization technology and linear polarization technology can overcome backscattering to a certain extent and improve the contrast and imaging distance of underwater objects (Dubreuil et al. 2013).

Line Polarization Technology

When the polarization direction of the illuminated target light (laser) and the polarization direction of the detector's front-line polarizer are both horizontal, the reflected light energy and scattered light energy of the object are approximately equal. And the contrast is too small to recognize the image. When the polarization direction of the linear polarizer is perpendicular to the polarization direction of the light source, the reflected light energy received by the detector is much larger than the scattered light energy. So the contrast of the image is related to the angle between the polarization direction of the linear polarizer and the polarization direction of the light source. When the angle is 0° , the image is blurred, and when the angle is 90° , the contrast is maximum, the image is clear.

Circular Polarization Technology

When the illumination source is right-handed circularly polarized light, the scattered light scattered by particles in water becomes left-handed circularly polarized light, that is, the scattered light becomes left-handed circularly polarized light. When the circular polarizer in front of the detector is right-handed, the backward scattered light of left-handed circularly polarized will be filtered out, and the incident right-handed circularly polarized light will be filtered out by the object. After reflection, the left-circularly polarized light and the right-circularly polarized light account for half of each, and the left-circularly polarized light will be filtered out by the right-circular polarizer in front of the detector. Only the right-circularly polarized light with the same polarization state can enter the imaging system through the polarizer for imaging, that is, the reflected light of the target entering the the detector is weakened and then backscattered light is basically eliminated. Using circular polarization imaging technology can reduce both backscattered light and target-reflected light entering the detector, but in different proportions. Most backscattered light is filtered out and most target-reflected light can

reach the detector, that is, the ratio of target-reflected light to backscattered light is improved, and the image quality formed on the detector is improved. To improve, the circular polarization technology can greatly improve the image sharpness.

The construction of the underwater polarization imaging system is simple and easy. Only a little modification is needed for ordinary underwater imaging instruments. Two polarizers are prepared. One polarizes the light source and the other analyzes the detected light signal. The light source modulated by polarizer emits fully polarized light, which illuminates the scene through the transmission of medium, and some light is scattered back to the detector by the medium particles. The sketch of underwater polarization imaging is shown in Fig. 4. The underwater polarization imaging system is connected with a circular polarizer on the outside of the digital camera and illuminated by a wide field of view polarization light. The analyzer detector is placed in front of the receiver. And two polarization images, which are perpendicular to each other, are collected. So the contrast and color of the underwater polarization image can be

Photoelectric Detection Technology in Underwater Vehicles, Fig. 4 Principle of underwater polarization imaging detection (Jin et al. 2011)

corrected. The contrast and color of the scene can be greatly improved.

Underwater Imaging Technology of Streak Tube

The principle of the streak tube imaging system is shown in Fig. 5. The receiving optical system imagines the incident light signal on the slit of the streak camera. The one-dimensional spatial light signal extracted from the slit is focused on the photocathode through the relay lens. The photoelectrons generated on the photocathode are accelerated by the accelerator and focused by the electrostatic focusing pole, and then enter the deflection system (deflection plate). There is a slope voltage that changes linearly at any time on deflection system. The photoelectrons entering the deflection system at different times are affected by different deflection voltage. When the photoelectron beam is enhanced by the image intensifier and reaches the fringe tube screen, it will spread along the direction of the slit and form a clear and visible fringe image on the screen. After the image processing system analysis, two-dimensional information of incident light signal can be obtained. That is, one-dimensional information of light intensity along slit direction changing with space and one-dimensional information of light intensity perpendicular to slit direction changing with time. A series of two-dimensional images of motion direction can be formed by sweeping with external mechanism, and three-dimensional data cube can be obtained by reconstruction. From the three-

dimensional data cube, the distance image of the observation direction dimension and the contrast image of the motion direction dimension can be obtained directly.

Modulation/Demodulation Laser Underwater Imaging Technology

Laser carrier intensity modulation (LCIM) technology is a feasible method for underwater range enhancement using coherent imaging detection. Early underwater coherent detection experiments usually used amplitude-modulated continuous laser to illuminate the target. And PMT was used to receive backscattered light and target-reflected light signals, and then the scattered light noise was partially removed by demodulating the amplitude modulated signal. Thus the detection distance could be extended to the detector scattered noise limitation. Subcarrier coherent detection technology is used to separate scattered light noise and reflected light signal in the time domain, thus generating target profile image or distance information.

As shown in Fig. 6, a high-speed modulator is used to load the microwave carrier onto the optical pulse, so that the laser pulse can carry microwave signals underwater. After reflection from the underwater target, it is accepted by a high-speed photoelectric detector and a carrier-modulated Lidar system is formed. The backscattering signal of sea water is formed by the superposition of reflected light from a large number of scatterers in water. Due to the random distribution of scatterers, the phase delay of each reflection is

Photoelectric Detection Technology in Underwater Vehicles, Fig. 5 Principle of streak tube imaging

Photoelectric Detection Technology in Underwater Vehicles,

Fig. 6 Block diagram of the modulated Lidar on optical carrier system (Zhang et al. 2011)

uncertain and the coherence is lost. In this case, after the superposition, the information of back-scattering at the modulation frequency is largely lost and transformed into a low frequency signal. The phase information of the modulation frequency is not lost because of the coherence of the target reflection, and the high frequency characteristic is maintained. So at the receiving end, the received signal of the system is output by the photoelectric detector, which is divided into two channels. One path passes through a low-pass filter to filter out the signal retaining modulation characteristics. And the other passes through a band-pass filter, whose central frequency is equal to the modulation frequency and whose bandwidth is very narrow, to filter out the scattering noise. The traditional Lidar signal and the modulated pulse signal can be detected on two independent channels of the digital oscilloscope. Finally, the detection data are analyzed by the computer.

Design of Underwater Photoelectric Detection System

The underwater imaging system consists of the underwater lighting system, the underwater imaging system, the data transmission system, the storage and display system, etc. (Shirai et al. 2000).

Underwater Lighting System

It includes the underwater lighting source, transmitting optical system, lighting source mounting bracket, underwater lighting power supply, and controller. Its function is to illuminate underwater targets to meet the need for underwater imaging for light energy.

Underwater Imaging System

It includes underwater high-speed imaging system, camera power supply, zoom focusing and focusing controller, camera controller, fixed and waterproof seals, and other structures. It is mainly responsible for the photoelectric conversion of the target and clear imaging.

Data Transmission System

It includes power supply, control and signal transmission, and so on. The Cam Link interface is converted into optical fiber relay transmission mode to realize long-distance transmission. The waterproof and sealed structure is used for power supply, control, and signal transmission.

Data Storage Display Processing System

It includes host computer, corresponding software and image recording equipment (acquisition card) mainly completes the functions of image storage and playback and can convert data stream files into multiple formats for analysis and preservation after the event.

Key Applications

In the military field, the underwater photoelectric detection system can be installed on underwater carriers such as submarines, lightning extinguishers, underwater robots, etc. It can be used for underwater target investigation, detection, and recognition, and can be used for mine detection, submarine detection, anti-submarine detection, submarine navigation, and collision avoidance. In the civil field, the underwater photoelectric detection system can be used for underwater engineering installation and maintenance, underwater environmental monitoring, lifesaving salvage, submarine geomorphological exploration, oil exploration drilling location determination, biological research, and other marine development.

Physical Properties of Sea Ice

Qingkai Wang and Zhijun Li
State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology, Dalian, China

Definition

Physical properties of sea ice are the fundamental nature of sea ice, including ice crystal structure, salinity, temperature, and density, which affect other properties of sea ice, such as mechanical, thermal, and electromagnetic properties. Sea ice is

a mixture of pure ice, brine, solid salt, and gas. Additionally, the relative contents of phase components change with ice temperature to keep phase equilibrium, which, in turn, affects other properties of sea ice. Therefore, ice porosity (the sum of the brine and gas volume fractions) is another important sea ice physical property. Sea ice can be considered as a medium between atmosphere and upper ocean, which cuts off the direct interaction between the latter two. The changes in the physical properties of sea ice impact the state of atmosphere and upper ocean. Energy exchanges among atmosphere, sea ice and upper ocean in forms of radiation and conduction. Mass exchange also occurs between sea ice and upper ocean such as the rejection of salt from ice into sea water when ice freezes. Sea ice physical properties have a considerable effect on these exchanges.

Sea ice exists in the polar regions perennially and further extends to subpolar sea areas in winter (Fig. 1). The production activities such as shipping and gas and oil exploration in the ice-covered water are affected significantly by sea ice. Structure in the ice zone must be designed to withstand extreme ice load. Sea ice mechanical properties are highly dependent on its physical properties. Given the vital function of sea ice on ocean engineering and global climate, a large number of field investigations have been carried out since the middle of the last century to study sea ice physical properties and their effect on ice mechanics. While most of them are conducted when air temperature is relatively high in late spring or summer

due to logistics, only a few of them have been carried out in winter or over a complete cycle.

Scientific Fundamentals

Sea Ice Growth and Crystal Structure

Generally, the seawater where sea ice forms has salinity more than 24.7 ppt leading to the freezing point being higher than the temperature corresponding to maximum density. Therefore, surface cooling of sea water produces an unstable vertical density profile in the upper water which further creates convective mixing. After the initial formation of continuous ice skim, the underlying ocean is isolated from the cold air so the subsequent ice growth is dominated by thermal conduction. Further crystallization occurs by direct freezing of seawater to the underside of the ice, which is called congelation growth. The above process is under calm conditions, while wind- or wave-induced turbulences in the open water areas can cause the ice skim over sea surface rafting and advection. The different grow histories result in varied grain textures. The observation of ice crystal texture is usually conducted by observing thin ice slices under crossed polarized light and photographed. An ice core is cut into several sections with thickness of a few centimeters. These sections are then attached to glass plates and thinned to a millimeter or less using a microtome. The preparation of ice slice should be cautious and is carried out under a low ambient temperature.

Physical Properties of Sea Ice, Fig. 1 Typical sea ice in the (a) Antarctic, (b) Arctic, and (c) subpolar region (Bohai Sea)

The most common ice crystal structures are granular and columnar grains (Fig. 2a, b). The granular grain usually has a sphere shape with size at the scale of $<10^{-2}$ m. Granular grain is usually associated with the formation of frazil ice which is mainly formed under a turbulent freezing condition. Four mechanisms have been identified responsible for turbulence (Jeffries et al. 1994). The first mechanism is the turbulence caused by wave and wind over open water. The second mechanism is double diffusion because of contact between two water masses with different salinity but both at their freezing point. The third mechanism is adiabatic decompression and resultant supercooling of water flowing from below ice shelves. The final mechanism is thermohaline convection initiated by surface cooling and freezing. In addition, frazil ice can also form by deformation processes. Some related processes are recognized (Lange and Eicken 1991). For example, newly formed frazil can appear at arbitrary places within ice because of ridging deformations. Rafting events can deposit newly formed frazil ice layer on the surface of lead underneath existing floes. Snow ice can also contribute the content of granular texture. Snow ice forms due to a heavy snow load submerging the ice surface below sea level, and sea-water floods and refreezes at the snow/ice interface. Snow ice is a common phenomenon in the Antarctic, but not very widespread in the Arctic. Recently, due to the thinning of Arctic sea ice and increase in total annual precipitation, the potential for snow ice is possibly increased. In

the Arctic, snow ice has a strong regional variability, and the largest potential is found in the Eurasian sector of the Arctic Ocean. Granular ice is typical isotropic of ice mechanics, i.e., the mechanical strength of granular ice does not depend on the loading direction. Columnar ice usually shows long vertically elongated crystals which are the result of thermodynamic congelation growth. Columnar grain has a larger size at a magnitude of $>10^{-2}$ m. Converse to the isotropy of granular ice, columnar ice usually shows anisotropy in ice mechanics. Such as there is an obvious difference between the uniaxial compressive strength in horizontal and vertical loading directions to ice surface, and the vertical strength is greater than horizontal strength. In the Arctic, first-year ice is often characterized as a thin granular ice layer at the surface underlain by a large fraction of columnar ice layer. While in the Antarctic, the ration between granular and columnar ice is reversed so that the granular ice accounts for more than columnar ice. While for multiyear ice, the crystal structure is much more complicated, which always shows discontinuities in crystal structure related to the changes in the size and shape of crystals. Apart from the common granular and columnar grains, there are also some other grains such as intermediate granular/columnar, mixed granular/columnar, inclined grains, and platelet grains (Fig. 2c).

Sea Ice Salinity

Ice salinity is usually expressed as the salts (in gram) contained in per kilogram of sea ice. It

Physical Properties of Sea Ice, Fig. 2 Typical crystal structures of Arctic sea ice: (a) columnar, (b) granular, and (c) mixed columnar/granular grains

is quoted as a mass fraction in per thousand or practical salinity units (PSU). Ice salinity is usually measured by extracting an ice core, cutting the core into sections, and placing in containers to melt. Ice salinity is then obtained by measuring the electrolytical conductivity of melted samples. Quick operation is necessary because the loss of brine from an extracted ice core occurs as it is removed from ice cover, especially in the warm parts of a core. It is estimated that the salinity underestimation in the bottom layers of an ice core ranges from 1 to 20 ppt in bottom layers for growing sea ice using core-based measurements (Notz et al. 2005). For summer sea ice, the underestimation may be only a few tenths averagely, but it is the main contributor to the scatter of measurement (Eicken et al. 1995). Notz et al. (2005) have developed a nondestructive technique to measure ice salinity in field for growing sea ice based on the impedance measurements between individual thin horizontal platinum wires. However, this method cannot be used to measure salinity in preexisting ice, but must be deployed in an open water before freezing.

The salinity of sea ice is usually much lower than that of the seawater from which it has formed. Most of the salt is rejected by sea ice at the advancing ice-ocean interface as it forms. Such rejection can be described using an effective

distribution coefficient which is proportional to ice growth rate. The remaining salt within sea ice is not trapped into the ice lattice but becomes concentrated in interstitial liquid brine. After its initial formation, sea ice salinity varies during winter because of processes of brine diffusion, expulsion, and gravity drainage. Of these processes, gravity drainage is considered to dominate the salt loss from sea ice during winter. When an ice floe is cooled, it often has cold top layers and warm bottom layers, which can cause an unstable density profile. The brine pockets at the top with higher densities moving downward. But, this process is dependent of the permeability of the sea ice (e.g., the connectivity of brine channels). It is often assumed that sea ice is permeable for brine transport through connected brine channels as brine volume fraction is above 5–7%. With entering into melt season, the meltwater flushing caused by surface melt can drive brine out of sea ice, which further decreases the salinity. Therefore, for a first-year ice, the vertical salinity profile turns from a “C-shape” during grow season to a “?-shape” after the onset of melt during a cycle (Fig. 3a, b). Multiyear ice is much less saline and usually shows a nearly fresh surface layer (Fig. 3c) because large brine drainage has already occurred in previous seasons. The sea ice bulk salinity is linearly correlated to ice thickness. For

Physical Properties of Sea Ice, Fig. 3 Typical vertical salinity profiles of (a) growing first-year ice, (b) melting first-year ice, and (c) multiyear ice

cold ice, there is a pronounced decrease in bulk salinity with increasing ice thickness. While for warm ice, there is a positive relationship between bulk salinity and ice thickness.

Sea Ice Temperature

Ice temperature is affected by meteorological conditions such as air temperature and solar radiation. Snow cover over ice surface can also affect ice temperature acting as an insulation. The temporal variation of ice temperature can be investigated using thermistor strings. Core-based measurement is also usually carried out in field observations to measure ice temperature at a certain point of time. A general seasonal evolution of ice temperature is as follows: (1) a cold front propagates through the ice in the fall; (2) sea ice becomes cold and grows in the late fall, winter, and early spring; and (3) sea ice warms to melting point the next summer (Perovich and Elder 2001). The ice/ocean interface temperature is at around melting point. While the air/ice interface temperature varies with air temperature, solar radiation varies with long-wave radiation. Additionally, snow cover acts as an insulation for ice leading to a warmer ice temperature. There is a spatial variation for ice temperature with different conditions of ice and snow conditions. Typically, thinner ice and deep snow produce warmer snow/ice interface and internal ice temperatures, while thicker ice and shallow snow result in colder snow/ice interface and internal ice temperatures. The related contents of phase components change as ice temperature varies. The brine volume must decrease or increase to keep phase equilibrium with decreasing or increasing ice temperature. Gas bubbles are expected to form meanwhile. Therefore, ice mechanical properties have strong relationships with ice temperature. Sea ice mechanical strength decreases with increasing ice temperature.

Sea Ice Density

Sea ice is a multicomponent medium consisting of pure ice and inclusions such as brine solid salt, and gas. The density of sea ice is controlled by the densities and contents of the pure ice, brine, and solid salt as well as the air content in ice. Furthermore, the relative content of each component is

dependent on the ice temperature. There are mainly four different techniques to measure sea ice density including mass/volume, displacement (submersion), specific gravity, and freeboard and ice thickness methods. The advantage and disadvantage of each technique have been presented detailed in Timco and Frederking (1996). Of these techniques, mass/volume method is commonly used in most field measurements by measuring the mass and dimensions of ice samples. For the core-based density measurement, there are two sources of error. The first is because of the measurement uncertainty, and the second is the brine loss during core sampling. The former can be deduced through an error propagation analysis. An accurate identification of the error due to brine drainage is not easy. The underestimation is estimated to range from 5% to 20% (Hutchings et al. 2015; Pustogvar and Kulyakhtin 2016).

Sea ice density has been reported over a wide range from 720 kg/m^3 to 940 kg/m^3 , with an average of approximately 910 kg/m^3 (Timco and Frederking 1996). This wide range is caused by, on the one hand, the multicomponent nature of sea ice, and in the other hand, the measurement uncertainty of dimensions. In general, density in the ice section above sea level is less than below sea level. This is because the drained brine pockets in the section above sea level can be replaced by air. For first-year ice, density ranges from 840 kg/m^3 to 910 kg/m^3 in the section above the waterline, and from 900 kg/m^3 to 940 kg/m^3 below the sea level. For multiyear sea ice, density ranges from 720 kg/m^3 to 910 kg/m^3 in the section above the waterline; while below the waterline, density has a same range as first-year ice. Sea ice density decreases with the increasing gas content. Timco and Frederking (1996) have calculated the density of gas-free ice with four different ice salinities (0, 2, 5, and 10 ppt) according to equations in Cox and Weeks (1983). It can be considered as the upper-limit value of ice density for an ice with specific temperature and salinity (Fig. 4).

Sea Ice Porosity

Porosity is defined as the sum of brine and gas volume fractions. Brine and gas inclusions are trapped when ice forms. Brine and gas volumes

Physical Properties of Sea Ice, Fig. 4 Calculated ice density versus ice temperature for four different salinities for gas-free sea ice in Timco and Frederking (1996)

vary with ice temperature. When ice is cooled, brine volume is reduced to keep phase equilibrium. Gas bubbles can also form by escaping from liquid brine because of decreased gas solubility. When ice warms, brine volume must be increased. At the same time, gas bubbles are expected to form in brine inclusions because lower density ice melting into higher density liquid forms a void within the inclusions. Brine and gas inclusions can be observed using the image process technique. Recently, computed tomography X-ray imaging method is employed to measure brine and gas inclusions. In addition, there are sets of mathematical formulae to calculate the volume fractions of brine and gas when the temperature, salinity, and density are known (Cox and Weeks 1983; Leppäranta and Manninen 1988). It is noteworthy that the calculation of gas volume fraction requires density with high accuracy. A small error of density measurement can produce a large error to calculated gas volume fraction.

Observations show that brine pockets are more vertically elongated and oriented than air bubbles. Brine pockets typically have mean major axis lengths of tenths of a millimeter, and air bubbles are much larger with mean major axis lengths of the order of millimeters. Measurements found that for multiyear ice, brine content ranges from 1% to

Physical Properties of Sea Ice, Fig. 5 Calculated brine and gas volume fractions against normalized ice depth for multiyear ice in the Arctic

15% by volume controlled by the thermodynamic equilibrium between the solid and liquid phases, and gas volume fraction decreases from >20% at the surface to <5% at the bottom (Eicken et al. 1995; Wang et al. 2020) (Fig. 5).

Applications

Because of the strong dependence of sea ice mechanical properties on its physical properties, the physical properties of sea ice are always used to determine the mechanical strength of sea ice. Several reliable formulae have been proposed between brine volume fraction or total porosity of sea ice and its mechanical parameters, such as tensile strength (Timco and Weeks 2010), shear strength (Frederking and Timco 1986), uniaxial compressive strength (Timco and Frederking 1990), and flexural strength (Timco and O'Brien 1994). It is then possible for a designer to estimate the ice strength parameters required by ice load evaluation based on these well-established relationships instead of performing mechanical tests.

In addition, sea ice physical properties, especially ice density, are directly involved in the ice load calculation for ice-structure interaction. For example, when an icebreaker ships in the level ice zone, its hull is covered by ice. Ice around the ship is lifted because of lighter density than water, which exerts additional resistance to the ship's hull. According to the commonly used ice resistance calculation method in Lindqvist (1989), ice density is a key input for determining the submerison component of total ice resistance. For ice interacting with a sloping structure, ice fragments or ice rubbles due to flexural failure of ice sheet will accumulate upon (for upward-slope structure) or below (for downward-slope structure) the slope. Accordingly, the weight or buoyancy of accumulated ice fragments exerts additional load on the structure. Therefore, ice density is involved in the calculation of ice load on sloping structures (ISO 2010).

For an ice-built structure, such as artificial grounded ice islands used for oil and gas exploratory drilling, it is important to monitor the ice temperature and density during construction (ISO 2010), as ice temperature and density largely affect its mechanical strength and thus the quality control of the entire program. The suggested measurement is mass/volume method for ice density and thermistor string for ice temperature. Ice strength decreases with increasing ice temperature. At high ice temperatures near melting

point, ice becomes soft and ductile; while at low ice temperatures well below melting point, it becomes strong and brittle. For an ice-built structure, it is usually used to support production equipment. Therefore, we must keep ice from warming up and make emergency measures before it warms. While, for an anti-ice structure, ice acts as the threat to structure safety, it is necessary to consider the ice strength at extreme low ice temperature during design.

Definition

The pile capacity refers to the maximum load that can be borne by a pile under load, to ensure that strength and stability of foundation soil and pile itself can be guaranteed and the deformation is within the allowable range.

Introduction

Pile foundation has been widely used in offshore engineering due to its high strength, large bearing capacity, and good durability (Kellezi and Hansen 2003). Like other foundation systems, strength and deformation are the two most important aspects that should be considered in design. That is, the pile foundation should be designed with high enough bearing capacity to carry the loads and without having excessive deformations at the same time. In this entry, bearing capacity of the pile foundation under both axial and lateral loads in cohesive and cohesionless soils is covered. The popular capacity design methods are introduced. The analytical methods for determining the soil reaction and pile performance under axial and lateral loading condition are presented in order to ensure the pile deformation, including the settlement, deflection, and rotation of the pile are within the acceptable serviceability limits and are compatible with the structural forces and movements.

Ultimate Axial Bearing Capacity in Cohesive Soils

Components of Axial Capacity

Pile is a typical deep foundation. The method to calculate the ultimate bearing capacity of deep foundation is thought to be suitable for estimation of bearing capacity of pile foundation in general.

The ultimate axial bearing capacity of deep foundation Q_u is generally composed of the end bearing capacity Q_b and the side friction resistance Q_s , that is:

$$Q_u = Q_b + Q_s \quad (1)$$

A_p is the gross end area of the pile,
 z is the depth below the original seabed.

The ultimate bearing capacity of the bottom of foundation is:

$$Q_b = q_u A_b \quad (2)$$

where

q_u is the unit bearing capacity of the bottom,
 A_b is the pile base area.

The ultimate shaft friction of the foundation is:

$$Q_s = f_s A_s \quad (3)$$

where

f_s is the unit shaft friction,
 A_s is the pile side surface area.

Several code methods are commonly used to calculate the pile axial capacity in cohesive soils, such as the API method (API 2000, 2008), the DNV method (DNVGL 2016), and the NGI method (Karlsrud et al. 2005; Karlsrud and Nadim 1990).

API Method

The API code is the specification of the American Petroleum Institute (API) for the planning, design, and construction of offshore fixed platforms.

The ultimate axial capacity of piles in compression Q_c in the API method is determined using the equation:

$$Q_c = Q_{f,c} + Q_p = f(z)A_s + qA_p \quad (4)$$

where

$Q_{f,c}$ is the shaft friction capacity in compression, in force units,
 Q_p is the end bearing capacity, in force units,
 $f(z)$ is the unit shaft friction, in stress units,
 A_s is the side surface area of pile,
 q is the unit end bearing at the pile tip, in stress units,

For open-ended pipe piles, the total end bearing capacity Q_p shall not exceed the sum of the end bearing capacity of the internal plug and the end bearing on the pile tip wall annulus. The weight and buoyancy of the pile soil-plug system should be considered when calculating the capacity of the pile foundation.

For pipe piles in cohesive soils, the unit shaft friction $f(z)$ at depth z can be calculated using the following equation:

$$f(z) = \alpha s_u \quad (5)$$

where

α is the dimensionless shaft friction factor, for clays,
 s_u is the undrained shear strength, in stress units.

The factor α can be computed as:

$$\alpha = 0.5\psi^{-0.5} \text{ for } \psi \leq 1.0 \quad (6)$$

$$\alpha = 0.5\psi^{-0.25} \text{ for } \psi > 1.0 \quad (7)$$

when $\alpha \leq 1.0$, $\psi = \frac{s_u}{p'_o(z)}$, where $p'_o(z)$ is the effective vertical stress at depth z .

For under-consolidated clays (clays with excess pore pressures undergoing active consolidation), α can usually be taken as 1.0.

The bearing capacity of unit pile end in clay can be calculated as:

$$q = 9s_u \quad (8)$$

The shaft friction, $f(z)$, acts on both inside and outside of the pile. The total axial resistance for pile compression is the sum of the external shaft friction, the end bearing on the pile wall annulus, and the total internal shaft friction or the end bearing of the plug, whichever is the lesser.

Details of the other code methods (DNV and NGI) can be referred to specific references.

Ultimate Axial Bearing Capacity in Cohesionless Soils

API Method

In the API method, the ultimate axial capacity of piles under compression is determined using the equation:

$$Q_c = Q_{f,c} + Q_p = fA_s + qA_p \quad (9)$$

For pipe piles in cohesionless soils, the unit shaft friction f is calculated using the equation:

$$f = Kp'_0 \tan \delta \quad (10)$$

where

K is the lateral earth pressure coefficient which is the ratio of horizontal to vertical effective stress,
 p'_0 is the effective overburden pressure at calculated points,
 δ is the external friction angle.

For unplugged open-ended driven pipe piles, it is usually assumed that the K values of tensile and compressive loads are all 0.8. For pile with soil plug or close-ended, the K value can be assumed to be 1.0. The capacity of open-ended driven pipe piles is usually lower than that of the closed-ended piles (Paik et al. 2003). If no further information is

available, Table 1 can be used to select the external friction angle. For long piles, f will not increase linearly with overlying pressure. In this case, restricted values of f are defined in Table 1.

The unit bearing capacity of pile end in cohesionless soil can be calculated as:

$$q = N_q p'_{0,tip} \quad (11)$$

where

$p'_{0,tip}$ is the effective overburden pressure at pile tip,
 N_q is bearing capacity coefficient, the values of which can be referred to Table 1.

CPT-Based Method

A simple method called CPT-based method is widely used for assessing pile capacity in cohesionless soils due to its better predictions of pile capacity and the advantages of simple, rapid, and relatively economic (Eslami and Fellenius 1997). This method is applicable for a wide range of cohesionless soils. The four commonly used CPT-based methods include the ICP method, UWA-05 method, Fugro method, and NGI method. More details of these methods can be found in the specific references (API 2011; Jardine et al. 2005; Clausen et al. 2005; Lehane et al. 2005a, b).

Soil Reaction for Piles Under Axial Load

The failure of the pile may be related to the bearing capacity, deformation, or settlement of the pile. Soil reaction is the result of interaction between the soil and the pile under load. It is necessary to analyze the soil reaction in order to ensure the pile settlement, deflection, and rotation of the pile are within the acceptable serviceability limits and are compatible with the structural forces and movements. The pile performance and deformation under both axial and lateral need to be predicted in design. The t - z curve is usually used to analyze the relationship between mobilized soil-pile shear transfer (t) and local pile displacement (z) at any depth. And Q - z curve is used to describe the relationship between mobilized end bearing resistance (Q) and axial pile tip displacement (z).

z is the local pile deflection,
 D is the pile diameter,
 t is the mobilized soil pile adhesion,
 $t_{\max}$ is the maximum soil pile adhesion or unit skin friction capacity.

The displacement value of 1% of the pile outer diameter (i.e., $z_{\text{peak}}/D = 0.01$) is generally employed to meet the design purposes. However,

there is great uncertainty for the case where the axial pile stiffness is critical for design. At this situation, it is feasible to take values of 0.25% to 2.0% of the pile diameter. It is necessary to pay attention to the shape of the t - z curve at displacements greater than $z_{\max}$ as shown in Fig. 1. Values of the residual adhesion ratio $t_{\text{res}}/t_{\max}$ at the axial pile displacement at which it occurs (z_{res}) are a function of soil stress-strain behavior, stress history, pipe installation method, pile load sequence, and other factors. Generally, the range of $t_{\text{res}}/t_{\max}$ is 0.70 to 0.90. Laboratory, in situ, or model pile tests can provide valuable information for determining values of $t_{\text{res}}/t_{\max}$ and z_{res} for various soils.

End Bearing Resistance-Displacement, Q - z , Curve

API Method

The ultimate bearing capacity of the pile foundation can be determined in accordance with the methods described in the previous sections. However, it usually requires a relatively large pile tip displacement to mobilize the full end bearing resistance. In sand and clay, a pile tip displacement as large as 10% of the pile diameter may be necessary for full mobilization. Definitive criteria and precise specifications are absent up to date.

API recommended a method as shown in Fig. 2 with data in Table 4 for both sand and clay. in which

z is the axial pile tip displacement,
 z_{peak} is the displacement to maximum soil pile adhesion or unit skin friction,
 Q is the mobilized end bearing capacity, in force unit,
 Q_p is the end bearing capacity, in force units,
 D is the diameter of the pile.

Lateral Bearing Capacity and Soil Response in Cohesive Soils

In addition to axial load, the lateral load also has an important influence on the pile foundation. For offshore piles, the significant lateral loads and moments are usually inevitable, especially for

Pile Capacity, Table 4 Data for pile end bearing capacity-displacement curve (API RP2A)

Pile Capacity, Fig. 2 Pile end bearing capacity-displacement curve

foundation such as anchor piles and monopile supporting wind turbines and small platforms. Therefore, the lateral bearing capacity of the pile foundation and the lateral resistance of the soil near the surface should be considered in the design of offshore pile foundation (Gourvenec and Randolph 2011). The method commonly used to design piles under lateral and overturning loads is based on the Winkler modeling method, commonly known as the p-y method (Byrne et al. 2015).

Nonlinear load transfer analysis method can be used to analyze the capacity and response of laterally loaded piles using appropriate load transfer curves (p-y curves) for different soil types (Fonseca 2015).

The p-y curve method is recommended to calculate the horizontal bearing capacity of pile foundations in API and DNV (Jin 1993).

Lateral Capacity and Response for Soft Clay

The following equations are suggested to estimate the lateral capacity of the pile in soft clay:

$$p_u = 3s_u + \gamma X + Js_u X/D \quad (12)$$

$$p_u = 9s_u, \text{ if } X \geq X_R \quad (13)$$

where

p_u is the ultimate horizontal bearing capacity,
 s_u is the undrained shear strength of soil,
 D is the diameter of the pile,
 γ is the bulk density of soil,
 J is a dimensionless constant determined by field tests, with a range of 0.25–0.5,
 X is the depth below the seabed,
 X_R is the depth below seabed to bottom of reduced capacity zone for uniform soils.

For the soil of constant strength with depth, the following formula can be obtained:

$$X_R = \frac{6D}{\frac{\gamma D}{s_u} + J} \quad (14)$$

For the nonuniform soil of strength increase

with depth, X_R can be solved by drawing the curves of the two eqs. (12) and (13). The first intersection point of the two curves is X_R . This relation does not apply to situations where intensity changes are irregular. In general, the minimum value of X_R is about 2.5 times the diameter of a pile D .

The relationship between lateral bearing capacity and displacement of piles in soft clay is usually nonlinear. For short term static loads, the p-y curve can be generated according to the data in Table 5.

Unless further information is available, the initial slope of the p-y curve of clay can be calculated by the following equation:

$$k = \xi \frac{p_u}{D(\varepsilon_c)^{0.25}} \quad (15)$$

where

ξ is the empirical coefficient,
 ε_c is the vertical strain at one-half the maximum principal stress difference in a static undrained triaxial compression tests on an undisturbed soil sample.

For normally consolidated clay, $\xi = 10$ is recommended, and for over-consolidated clay, $\xi = 30$ is recommended.

where

p_u is the ultimate lateral capacity, unit of pressure,
 p is the mobilized lateral resistance, unit of pressure,
 y_c equals $2.5 \times \varepsilon_c \times D$,
 y is the local pile lateral displacement.

Lateral Capacity and Response for Stiff Clay

Hard clay has greater brittleness than soft clay, despite it has nonlinear stress-strain relationship (API RP2A). When establishing the stress-strain curves of hard clay and the p-y curves under cyclic loading, it is necessary to make a proper judgment on the rapid weakening of the bearing capacity of hard clay under large deformation.

Lateral Bearing Capacity and Soil Response in Cohesionless Soils

API Method

The ultimate lateral bearing capacity of pile in sand can be computed by the following equations. Eq. (16) is for the capacity of shallow soil, and Eq. (17) is for the deep soil. At the given depth, the ultimate bearing capacity should be the minimum value of the calculated p_u :

$$p_{us} = (C_1X + C_2X)\gamma'X \quad (16)$$

$$p_{ud} = C_3D\gamma'X \quad (17)$$

where

p_u is the ultimate resistance, units of pressure,

γ' is the submerged soil unit weight,

D is the pile outside diameter,

X is the depth,

C_1, C_2, C_3 are coefficients given in Fig. 3.

The lateral bearing capacity–displacement relationship (p-y) of sand is nonlinear. In the absence of reliable data, approximate values at any depth can be approximately determined according to the following equation:

$$p = Ap_u \tanh\left(\frac{kX}{Ap_u}y\right) \quad (18)$$

where

p is ultimate lateral bearing capacity at depth X ,
 k is the rate of increase with depth of initial modulus of subgrade reaction which can be got from Table. 6,

y is the lateral deflection at depth X ,

Pile Capacity,

Fig. 3 Coefficients C_1, C_2, C_3 , as function of ϕ in API method

Pile Capacity, Table 6 Rate of increase with depth of initial modulus of subgrade reaction k (API RP2A)

ϕ	k	
	MN/m ³	(lb/in ³)
25°	5.4	20
30°	11	40
35°	22	80
40°	45	165

X is the depth below the original seabed,

A is a factor to account for static or cyclic loading conditions as follows:

$$A = \begin{cases} 0.9 & \text{for cyclic loading} \\ \left(3 - 0.8 \frac{X}{D}\right) \geq 0.9 & \text{for static loading.} \end{cases} \quad (19)$$

Other Considerations

Pile foundation in offshore engineering is a complex system, from the installation process to loading stage. The contents of pile capacity in this entry only cover the methods for common and simple situations. Some methods, especially the code methods, are based on specific databases. Most of the databases may comprise piles of smaller length and diameter compared with piles in practical projects (Randolph et al. 2005). Some significant issues such as friction fatigue and progressive failure for long and large diameter pile may not be fully integrated in the methods. As a result, caution should be exercised when the selected methods are applied to some circumstances with special conditions. Another significant point is that cyclic loading is an important feature and has critical effects on the capacity of offshore pile foundations (Leblanc et al. 2010). But due to the complexity, cyclic loading is not covered here. Also, some other issues related to the capacity of foundation such as the pipe-pile plugging, pile in carbonate soils, grouted pile in rock, pile groups and so on are not included in this entry. Appropriate paper and books can be referred to address these specific issues.

Definition

Submarine pipelines and risers are an important part of offshore oil and gas development engineering, and the seabed pipe-soil interaction is one of the key issues in the design of pipelines and risers. According to the laying state and operation state of pipelines and risers, the results show that the seabed as the foundation of supporting must provide sufficient support to ensure the stability of pipelines and risers. The research on pipe-soil interaction is to accurately predict the fatigue life of pipeline by describing the buried depth and internal force of pipeline in soil and correctly evaluating the effect of soil on pipeline resistance. This kind of research is of great significance to the stability, safety, and economy of pipelines and to the improvement of relevant design codes.

Seabed pipe-soil interaction affects various aspects of subsea pipelines and risers during installation and operation, which include the touchdown point (TDP) of the steel catenary risers (SCR) directions, bearing capacity of pipeline and lateral buckling, etc. In this chapter, the research status by scholars in recent years will be introduced in detail.

Soil Types and Classification

Soil parameters along the pipeline route are needed for modeling pipe-soil interaction, which can be obtained by carrying out geophysical and

geotechnical surveys. The soil can be classified by grain size or its plasticity and cohesion. Soils with particles larger than about 0.05 mm are called coarse grained (sands and gravels), while soils finer than this size are called fine grained (silts and clays).

Soil is a porous media material comprising solid particles with void spaces containing gas and water. In subsea environments, the water pressure is generally high enough that gas is forced into solution and the soils are saturated with water. Soil behavior depends on the rate at which load is applied to the soil, and generally can be categorized as “drained” or “undrained” behavior (Bai and Bai 2014). If the rate of load is greater than the rate at which pore water in the interparticle voids is able to move in or out of soil interparticle voids, then the soil is said to behave in an undrained manner. If the rate of loading is slower than the rate at which pore water is able to move in or out of soil interparticle voids, the soil is said to behave in a drained manner.

Dynamic Pipe-Soil Interaction at TDP

The use of SCR in deepwater developments is increasing, and most of the structural damage of SCR occurs in the so-called TDP where the pipe takes off and lands repeatedly on the soft soils generally encountered in deepwater (Fig. 1).

Different pipe-soil interaction models are used in TDP numerical analysis. The rationality and reliability of these models directly affect the accuracy and efficiency of calculation results. At

present, the most widely used pipe-soil nonlinear models are proposed by Aubeny and Biscontin (2009) and Randolph and Quiggin (2009), which are abbreviated as AB model and RQ model, respectively. Both of them are based on a large number of test results. AB model is mainly developed from the large-scale model test of Langford and Aubeny (2008), while RQ model is summarized from the centrifuge test results carried out by Hodder et al. (2008). Bridge summarized a nonlinear model based on the test results of STIDE and CARISIMA JIP. It was pointed out that the process of pipe-soil interaction can be divided into four stages: penetration, uplift, suction, and reintegration. RQ model refers to the full-scale field test results of Bridge et al. (2004). Different pipe-soil interaction models are used in numerical analysis. The rationality and reliability of these models directly affect the accuracy and efficiency of calculation results.

As shown in Fig. 2, there are four stages in AB model: initial penetration stage (power function backbone curve), upper pull-up stage (hyperbolic function elastic rebound curve), partial detachment stage (third order polynomial curve), complete detachment stage and repenetration stage (third order polynomial curve). The pipe-soil separation point in AB model can describe the formation of grooves under the pipeline, which is in accordance with the test results, but the effect of soil strength on cyclic weakening is not considered.

As shown in Fig. 3, RQ pipe-soil interaction model describes four different states of pipe-soil interaction: noncontact, initial penetration, uplift

Pipeline Soil Interactions, Fig. 1 TDP of SCR (Fontaine 2006)

Pipeline Soil Interactions, Fig. 2 P-y curve in AB model (Aubeny and Biscontin 2009)

Pipeline Soil Interactions, Fig. 3 P-y curve in RQ model (Randolph and Quiggin 2009)

and repenetration. The curve describes the change of resistance of soil model with the buried depth of pipeline. Curve 1 is the initial penetration, curve 2 is the pull-up process, and curve 3, 4 are the process that the pull-up force increases first and then decreases. Curve 7 represent the repenetration process, which indicates that the soil stiffness decreases when repenetration occurs. As the burial depth continues to increase, the repenetration curve gradually merges into the

initial penetration curve. The variation of resistance in RQ model is related to the pipeline loading path, which can describe the disturbance degree of pipeline movement on the bottom soil to a certain extent. During the interaction between pipeline and seabed, plastic deformation occurs in the soil beneath the pipeline, which explains the reason why part of the soil is pushed by the pipeline to both sides to form a bulge and groove. However, the RQ model does not consider the

effect of pipe grooving when simulating upsetting.

You (2012) has improved the AB model by considering soil weakening with power function, incorporating the repenetration curve into the initial penetration skeleton line with a new formula, and adopting different mathematical formulas for each loading and unloading stage. Aubeny et al. (2015) based on the results of Langford and Meyer's tests (2010), a new weakening model was formed by considering soil weakening in AB model. The three stages of initial penetration, elastic rebound, and reloading were used to describe the nonlinear behavior of soil, and the effect of soil weakening was taken into account in the new model.

Vertical Pipe-Soil Interaction of Pipeline

Pipeline on the seabed will has preliminary embedment which called pipeline penetration. The pipeline penetration is affected by the following fundamental issues, such as geotechnical statement, pipeline laying operations, and scouring from the actions of waves and current. Figure 4 illustrates the definitions of parameters used in the model of pipe penetration (Bruton et al. 2008). To prevent the vertical movement of a pipeline in soil, the pipeline should be neither heavy enough to sink nor light enough to float. The pipelines to be buried should be checked for possible sinking or floatation. Sinking should be considered with maximum content density, such as water filled, and floatation should be considered with minimum content density, such as air filled.

The vertical pipe-soil interaction during pipeline penetration can be modeled by soil spring based on Winkler foundation beam theory

(Limura 2004) or shell model (Yatabe et al. 2002). The effects of deformation mode and the maximum strain of pipelines in different states can be obtained. A module used for assessing pore pressure accumulation in the seabed was designed by Bonjean et al. (2008). The module could assume both the uplifting force exerted on the pipeline and the corresponding soil resisting force.

The process of pipeline penetration into the seabed was analyzed by Chatterjee, using the means of large deformation technology (Chatterjee et al. 2012). Considering the effects of strain softening, strain rate, and soil uplift, the formula for calculating the vertical resistance of pipeline was put forward, and a breakthrough in theoretical calculation was achieved.

Rossiter and Kenny (2012) examined pipe-soil interaction events during oblique lateral-vertical soil movements using plane strain finite element analysis. The results from this study provide a technical framework to assess complex loading events, such as coupled ice keel/seabed/pipeline interaction. Later, the discontinuous medium contact treatment method in discontinuous deformation analysis was used to simulate buried pipelines, and the feasibility and validity of solving pipe-soil contact with finite element method were discussed (Na et al. 2013).

White and Randolph (2007) described the relationship between penetration resistance and the vertical and lateral resistance of pipelines, using both in situ methods in the form of cylindrical (T-bar) and spherical penetrometers. The relationship taking account of the depth of burial and cycles of movement. Two new models of interaction between pipelines and seabed have been proposed: non-weakening model and weakening model (Jiao 2007). In both models, the main line

Pipeline Soil Interactions,

Fig. 4 Pipeline penetration in soil (Bruton et al. 2008)

is used to describe the pipeline penetration, the boundary curve is used to define the resistance-displacement relationship of the pipeline in large displacement, and a series of formulas are used to describe the resistance-displacement curve in the cyclic process.

A predictive model for estimating the compression and shear stresses around a buried pipeline in static conditions has been developed for determining stresses around a buried pipeline and verified using the Alyeska and Soil Box tests (Andrenacci and Wong 2012). Advanced pipe-soil interaction techniques that used to demonstrate benefits that can be realized on typical projects to reduce pipeline walking predictions and the associated mitigation measures were presented (White et al. 2015). Aubeny et al. (2015) formed a new weakening model considering soil weakening based on the test results of Langford and Meyer (2010). It used three stages of initial penetration, elastic rebound and reloading to describe the nonlinear behavior of soil. The interaction between soil and pipeline was studied by controlling the change of soil stiffness during uplift and repenetration.

Computational fluid dynamics (CFD) was used to consider seabed soil as fluid and to establish a follow-up grid in a certain area around the pipeline (Hawlder et al. 2015). The computational method requires less computational resources than RITSS and CEL methods, and can also consider strength weakening and strain rate effect. Another research present details of a novel 2D pipe-soil-fluid (PSF) interaction algorithm, which has been developed to offer a more accurate model of the evolution of soil profiles around the pipeline (Griffiths 2012). A large number of parametric 2D CFD models have been run to generate

seabed shear stress profiles as a function of seabed and pipe geometry under different wave and current flow conditions. The PSF model has been designed to minimize computational cost but still enable the profile of the soil around the pipe to be tracked.

Lateral Pipe-Soil Interaction of Pipeline

Pipeline on-bottom stability design is conventionally based on the static balance between hydrodynamic forces and the soil lateral resistance forces, as shown in Fig. 5. Verley and Lund (1995) developed a soil resistance model applicable for pipelines laying on clay soils. Brennodden and Stokkeland (1992) performed some full-scale model tests for the Troll Phase 1 development. The results of these model tests revealed a significant increase in peak soil resistance (Bai and Bai 2014) (Fig. 6).

Based on theoretical analysis and experiments of lateral buckling of a pipe, Palmer and Baldry (1974) correctly interpreted the reason why lateral buckling can occur in a pipe and proposed an analytical formula for the critical pressure. Hobbs (1984) studied the lateral buckling of a perfect straight pipeline on the basis of related work on railroad track and proposed five buckling modes which may occur in the process of lateral buckling. Analytical formulas for critical force, wavelength, and amplitude corresponding to every buckling mode are also presented. Taylor and Gan (1986) considered the initial imperfections and proposed analytical formulas for critical forces of lateral buckling corresponding to mode 1 and mode 2. Finite element (FE) analysis was

Pipeline Soil Interactions, Fig. 5 Soil spring model

Pipeline Soil Interactions,

Fig. 6 Lateral buckling under cyclic thermal load (Bai and Bai 2014)

used to study the lateral buckling responses of submarine pipelines (Liu et al. 2014), some formulas were proposed to calculate the critical force of lateral buckling. The initial imperfection parameters (initial wavelength and maximum amplitude) are included in these formulas.

The stability of submarine pipeline during service is studied by hydrodynamic loading method (Fuping 2001). And the test reflects the coupling effect among wave, pipeline, and seabed. It is found that the lateral instability of submarine pipeline generally goes through four stages: complete stability, sand bed erosion, slight displacement of pipeline, and pipeline instability. It is also found that loading history, soil parameters, and initial settlement of pipeline all affect the stability of pipeline. On the basis of experiments, the empirical relationship of wave-tube-soil interaction for pipeline stability is preliminarily established.

Some results simulated the seabed by adding a nonlinear spring under the linear elastic pipeline, and put forward the corresponding analytical model of pipe-soil interaction (Aubeny and Biscontin 2008). The nonlinear spring takes into account the nonlinearity of the load-displacement relationship of the seabed and the separation of pipe and soil. A physical model was used to understand the mechanisms of interaction between pipe and soil through a lateral visualization, and then to simulate the pipe response under combined vertical and horizontal loads (Orozco-Calderon et al. 2012). This entry concentrated on

the results obtained using sideswipe tests with large and short horizontal displacements, and obtained an experimental yielding envelope of the pipe.

In the recent years PETROBRAS has developed several projects in deepwater areas of the Santos and Campos Basins, offshore Brazil, where soft clay is predominant. This has motivated the development of an extensive experimental test program for pipe-soil interaction, aimed at increasing the design reliability of subsea pipelines with lateral buckling (Cardoso and Silveira 2010). A new model presented was based on full-scale tests developed at the Institute of Technological Research (IPT) installations over the last 3 years. The experimental results were used to develop a model for the lateral residual friction factor based on dimensionless groups that govern the problem. The aim of this model is to improve knowledge obtained by the industry in recent years, mainly by the JIP SAFEBUCK I and II programs.

Another study concerned the lateral buckling critical force of a submarine PIP (pipe-in-pipe) pipeline with one symmetrical initial imperfection on soft foundation (Xinhu et al. 2018). On the basis of 3D beam elements, tube-to-tube interaction elements and pipe-soil interaction elements, 3D finite element model were built for a length of submarine PIP pipeline. The simple empirical formula was proposed to calculate the lateral buckling critical force of a submarine PIP pipeline based on dimensional analysis and finite element

results, and the case study was carried out to verify the obtained empirical formula and the results manifest its good accuracy.

Definition

Ship piping system refers to the piping system of the ship, which includes all the pipelines, accessories, machinery, equipment, and appliances used to transport fluids. Ship piping system is key to ensuring the normal operation of the ship power plant, deck outfit, ballast systems, and living facilities and to the safe navigation of ships. It is also an important guarantee for the service life of ships.

For shipbuilding, ship piping is one of the largest engineering projects of both processing and manufacturing in the workshop and installing and debugging in the field (Rao et al. 2020). For example, the ship piping of a 10,000 DWT grade bulk carrier can account for about 25% of the total workload of shipbuilding. Another example is that piping system of a chemical product transport ship includes dozens of systems, nearly a 1000 types of pipe specifications, and tens of thousands of pipes. Therefore, the processing and assembly of ship pipes is an important part of the construction of the ship structure.

In modern shipbuilding, pipe system production is considered as an important processing step

in the manufacturing of shipbuilding enterprises. There are many types of pipes with different models and different uses. According to their different transmission media, pipe systems can be divided into steam pipe system, fuel oil and lubricating oil pipe system, compressed air pipe system, and cargo oil and liquefied gas pipe system. According to their different functions, pipe systems can be divided into high pressure pipe system, nuclear power pipe system, high temperature pipe system, low temperature pipe system, chemical medium pipe system, etc. (Xu 2011). According to their different materials, pipes can be divided into three categories: steel pipes, non-ferrous metal pipes, and nonmetallic pipes.

Introduction

Pipe Processing Technology

The pipe processing workshop is the place where the shipbuilding enterprise processes and manufactures ship pipes. In the modern shipbuilding model, pipe processing workshop is arranged with the principle of group technology, thus establishing a production operation system guided by the principle of manufacturing “intermediate products” of the ship. The pipe processing workshop first decomposes the pipe fitting production tasks according to pipe processing drawings and part lists issued by the pipe design department, together with the tray plan of the piping tray. Then the workshop distributes the decomposed production tasks to different teams, each of which, according to its task, receives the raw materials from the raw material warehouse of the pipe processing workshop and then completes the pipe processing according to the production process of the pipe processing drawing, including the processes of cutting, bending, reshaping and positioning, welding, polishing, testing, and surface treatment (Li 2016).

Cutting

Correct cutting is the first step in the pipe processing work. Before cutting, we obtain the theoretical calculation length of the pipe from the design drawing. The cutting length is considered

as the overall length of the bending pipe, which is theoretically the overall length of both the straight pipes and the elbow arcs. When the pipe is being bent, the arc length of the elbow part is slightly elongated due to plastic deformation of the material, so the actual cutting length should be slightly shorter than the theoretical length.

Elongation is an experience data, which depends on the pipe material, diameter, wall thickness, bending radius, bend size, and the choice of hot or cold bending. Generally, for a pipe of a certain specification and material, the elongation is proportional to the bending angle α . At present, the actual cutting length of a pipe in the factory is usually its theoretical cutting length, and the elongation will be cut off when the pipe is reshaped and positioned. However, if the "welding prior to bending" technology is adopted, the elongation must be considered, usually based on the experience data obtained from the test (Fan 2018).

Generally, pipes are cut by the sawing machine or through oxy cutting, but after oxy cutting, iron oxide residue and spatter must be removed. Non-ferrous metal pipes and HDR stainless steel pipes should be cut by machine saw or the handsaw.

1. Gas cutting

Gas cutting of metals (in reality, oxygen cutting) is currently the most commonly used cutting method for ship piping. Its process is described as follows: first, the metal at the cutting slit is heated with a preheating flame, so that the metal temperature at the starting point of the slit rises to the ignition point (the ignition point of the metal in pure oxygen); then the oxygen flow with high pressure is released and causes the metal to burn (violent oxidization); the slag generated by the burning is immediately blown away by the airflow; continue this process and a smooth slit will be formed in the metal to separate it.

2. Plasma cutting

Plasma arc cutting is a processing method that uses the heat of a high-temperature plasma arc to locally melt (and evaporate) the metal at the slit of the workpiece and uses the momentum of the high-speed plasma to remove the molten metal to form a cut. Plasma cutting,

with different working gases, can cut all kinds of metals that are difficult to cut by oxygen, especially nonferrous metals (stainless steel, aluminum, copper, titanium, and nickel). Its main advantage is that it can reach a high speed when cutting the metal of limited thickness. Especially when cutting ordinary carbon steel sheet, the speed of plasma cutting can be five to six times that of oxygen cutting, with a smooth cutting surface, limited thermal deformation, and a smaller heat-affected zone.

Pipe Bending

Rotary draw bending is the main form of cold bend and is also used by most NC pipe bending machines. The pipe bending performed on the pipe bending machines is often divided into two categories: bending without mandrel and bending with mandrel. In order to prevent excessive flattening of the cross-sections of the bending part, the method of bending with mandrel is often used for pipes with relatively thin walls, while the method of bending without mandrel is used for pipes with relatively large wall thickness or with low or even no requirement for cross-section flattening. The schematic diagram of the processing by pipe bending machine is shown below (Fig. 1).

The bending forming process is completed with the cooperation of multiple molds. The bending radius of the pipe and the cross-section shape of the bending segment are determined and controlled by the bending die. The clamping die fixes the front end of the pipe on the bending die and gives the pipe a certain clamping force to ensure that the three-in-one rotation of the pipe, the bending die, and the clamping die completes the bending of the pipe. The pressure die supports the outside of the pipe and can move together with the pipe to boost the pipe, thus limiting the decrease in the thickness of the pipe outer wall and the increase in the thickness of the pipe inner wall at the bending segment. The main function of the antiwrinkle die is to reduce the wrinkles caused by pressure on the inner side of the bending position, so an antiwrinkle die must be used in the bending with higher requirements for inner wrinkling or in the bending of large-diameter thin-walled pipes. The mandrel is mainly used in

Piping Technology, Fig. 1 The schematic diagram of the processing by pipe bending machine

the bending of pipes with relatively small wall thickness, to prevent excessive flattening of the cross section of the bending segment, and the mandrel also has a great influence on the thickness change of the outer wall of the pipe and the rebound of the pipe (Wu 2016).

Pipe Reshaping and Positioning

The pipe reshaping and positioning by the pipe reshaping machine is a method of installing the slip-on welding flange on the main pipe. Based on the information of the pipe parts drawing, the pipe reshaping machine is moved to an appropriate position, and a flange is installed on the template, with a steel ring inside the flange, the thickness of which equals to the weld end distance. Then both ends of the pipe to be formed are set into the flange, and the position of the pipe is adjusted according to the drawing. Then the flange positioning work begins to be performed (Fig. 2).

Platform pipe reshaping and positioning is another method of assembling slip-on welding flange on the main pipe. The method of marking on the flange surface is used based on the flange bolt hole angle data in the piping parts drawing, and with the help of tools such as flange ruler, level bar, angle ruler, and plumb, the pipe is set on the platform according to certain requirements in order to perform flange positioning. General requirements for pipe reshaping and positioning are that

the end of the pipe should be flush; the surface of the pipe should be clean; the gap between the pipe and the accessories should be uniform and meet the relevant process requirements.

Welding

1. Workshop welding of ship pipe fittings

Ship pipe fittings refer to semi-finished pipe fittings of all types, batches, materials, and sizes that are welded and produced in the workshop and then sent to the hull block for group welding. The biggest advantage of preparing semi-finished pipe fittings under the conditions of workshop production is that the pipe accessories are easy to assemble, and the functions of various automatic pipe welding equipment and auxiliary welding equipment are given full play. The satisfactory welding quality could also be achieved in some occasions where manual welding is used.

As shown in Fig. 3a, an all-position automatic pipe welding machine is used in the workshop to perform pipe-pipe butt welding after preheating. As shown in Fig. 3b, a large all-position automatic pipe welding machine is used in the workshop to perform large-diameter pipe-pipe butt welding. As shown in Fig. 3c, a narrow-gap gas welding machine is used in the workshop to perform thick-walled pipe-pipe butt welding.

- (1) Column; (2) screw rod;
(3) template; (4) hand grip;
(5) swivel plate;
(6) pedestal; (7) guide rail;
(8) guide frame; (9) brake

2. On-site welding of ship pipe fittings

On-site welding of ship pipe fittings (Fig. 4) refers to the welding of pipe fittings on the sites of hull block. On-site welding of ship pipe fittings is generally performed in the form of pipe-pipe butt joints, but various welding positions may be required (Figs. 5 and 6), so the automatic pipe welding machines are usually used to ensure high welding quality and reduce welders' labor intensity.

Welding of ship pipe fittings can be summarized into several types: the first type is pipe-pipe butt joint (Fig. 7), pipe-flange butt joint (Fig. 8), and pipe-pipe multipass butt joint (Fig. 9). This type of ship pipe fittings with butt welds are most widely used in ship piping system, and for this type, the standardization and serialization have been formed in the aspects of materials, models and sizes, pressure ratings, etc., for the pipes, pipe flanges, pipe elbows, three-way pipes, and other accessories within the common size range, as shown in Fig. 10.

The other type is the branch pipe welding, which is rare among ship pipe fittings within the common size range, because this type of joint can

generally be replaced by a three-way pipe joint; If the branch pipe welding becomes necessary, it must be used for the joint of a non-standardized pipe (or fittings) or a special thick-walled pipe (or fittings) with a tube, which is usually called saddle-shape weld joint in the industry.

The most widely used automatic arc-welding equipment in the on-site installation of ship pipelines (block pipe system) is the all-position automatic pipe welding machine. It is an automatic arc welding equipment which can weld fixed pipe joints (with pipe fittings not rotating) at all positions (the meaning of "all-position" is shown in Fig. 11).

In Fig. 11, the butt weld pipe joint to be welded does not rotate, but the welding gun (usually a TIG welding gun, namely, an argon tungsten-arc welding gun) rotates more than 360° around the centerline of the groove of the pipe joint. In this way, a variety of welding positions on the pipe surface could be reached by the welding gun: flat welding position, vertical down welding position, overhead position, vertical upward welding position, and multiple welding positions among these four welding positions; because to complete the circumferential weld of a pair of butt-welded

(a)

(b)

(c)

Piping Technology, Fig. 3 The automatic welding method of centralized pipe systems in the workshop

pipes, the welding gun will be at a variety of welding positions, so this arc-welding equipment is called an all-position automatic pipe welding machine. It is a highly automated mechatronic arc welding equipment, because the completion of the welding of the circumferential weld of a pair of pipes requires not only that the welding head rotates around the pipe at a uniform welding speed, but also that the welding current, shielding gas, filler wire, and cooling water are connected to

the corresponding parts of the welding head, as shown in Fig. 12.

In order to meet the process requirements of different arc welding and ensure excellent welding quality, sometimes the welding head is required to swing laterally during welding. Therefore, from the appearance, there are many wires, water pipes, gas pipes, and cables led to the pipe welding machine. In order to realize the smooth “three links” of water, electricity and gas, the

Piping Technology, Fig. 9 Pipe-pipe multipass butt weld joint

Piping Technology, Fig. 11 The schematic diagram of the all-position welding machine

Piping Technology, Fig. 10 Standard fittings of several pipe flanges

wires, water pipes, gas pipes, and cables of the pipe welding machine must be reasonably arranged. Obviously, the smaller the diameter of the pipe being welded is, the smaller the volume of the pipe welding machine is, but the higher the precision for the mechatronics system of the pipe welding machine is required to be, and the higher the flexibility of the pipe welding machine is required to be.

Pipe-Piece Family Manufacturing

The pipe-piece family manufacturing method is another successful application of group

Piping Technology, Fig. 12 The travel carrier pipe welding machine

technology by Ishikawajima Harima Heavy Industries of Japan. In an ideal situation, the various machines needed to manufacture a particular intermediate product family should be set into a group to form a production line. The group of machines can complete all processes as a predetermined process unit, and this method is called “process classification.” This method replaces the

traditional process design method required to manufacture parts. When this method is applied to a pipe workshop, it is called a pipe-piece family manufacturing method.

The pipe-piece family manufacturing method is a comprehensive method that simplifies the manufacturing process of the pipes of mixed varieties and mixed batches, such as vent pipe parts manufactured together with other pipe parts. This method requires more complicated plans and schedules than traditional, inefficient, and system-oriented plans and schedules. With this method, mass-manufacturing mode could be adopted for manufacturing complicated varieties of ship pipes, and piping part design, manufacturing technology, and production management could be reasonably arranged, so that the general shipbuilding productivity could be better improved by piping engineering, and the productivity of pipe fittings could be greatly improved, too (Xie 2011).

Polar Acoustics

Jingwei Yin

College of Underwater Acoustic Engineering,
Harbin Engineering University, Harbin, China

Polar acoustics (also known as Arctic Ocean acoustics) mainly studies the underwater acoustic environment in the polar region and adjacent sea areas and is a branch of hydro-acoustics. The significant research began during the Cold War (1947–1991) with the advent of the nuclear submarine. The main contents of polar acoustics include the marine environment noise under the ice cover, reverberation characteristics, the characteristics of underwater acoustic channels, and underwater acoustic signal processing. Based on these understandings, polar acoustics are well applied in the polar region, named polar acoustics technology.

The presence of ice and its spatial and temporal variability are the main characteristics of the Arctic Ocean that affect the underwater acoustic environment. This phenomenon is particularly prominent in Arctic Ocean, unlike the Antarctica that is covered by ice perennially. The growth and ablation of sea ice make the Arctic acoustic environment unique and interesting.

Ambient Noise

The ambient noise in the Arctic Ocean consists of many types and is different from any other sea

area. There is few shipping noise due to less water traffic. Sea ice movement, earthquake, and biological activity are the mainly sources of Arctic Ocean ambient noise.

The frequency spectrum range of the Arctic Ocean ambient noise is approximately 1 ~ 1000 Hz, and the peak occurs mainly at two specific frequencies of 15 Hz and 300 Hz (Dyer 1988). The peak at 15 Hz is believed to be generated by ice ridge activity as shown in Fig. 1, and 300 Hz is considered to be caused by temperature-induced thermal cracks. These two types are the main sources of Arctic noise. Zakarauskas summarized the Arctic ambient noise:

1. Pressure Ridging Noise

Floating ice is affected by the wind and ocean currents and squeezed to form ice ridges. Collisions, squeezing, and friction between sea ices produce low-frequency noise during the process (Greening and Zakarauskas 1994a).

2. Thermal Cracks Noise

As the season change, shrinkage or expansion occurs when the temperature is greatly different

between the upper and lower surface, resulting in thermal cracks (Greening and Zakarauskas 1994b). Thermal cracks are subtle noise phenomenon that takes place on the surface of the ice layer. It usually occurs during the night, and maintenance is 0.05 ~ 0.1 s. Different from the noise produced by the formation of ice ridges, the frequency spectrum of the thermal crack noise is relatively flat, and the noise produced by the ice ridge is mainly in the low-frequency range.

3. Snow Noise

The polar high atmospheric pressure exists for a long period over the Arctic Ocean, and the east wind prevails in winter. Snow noise become the main noise in the quiet ice area such as huge ice cap in winter and spring. The wind blows the snow particles on the ice cap to rub against it, and then the sound enters the water through the ice layer, creating snow noise. The frequency of this noise is between 2 Hz and 2 kHz.

4. Earthquake Noise

P wave generated by earthquakes have a frequency of 0.1 ~ 5 Hz and carry little energy. The

Polar Acoustics,
Fig. 1 Frequency
spectrums of pressure
ridging noise (Greening and
Zakarauskas 1994a)

T wave produced by the earthquake has more energy, and the frequency band is 5 ~ 60 Hz. Such waves propagate from the bottom of the sea to the water and reach the ice. This type of noise is more difficult to distinguish from long-range ice ridge forming noise, since the frequency bands of the two are similar.

5. Biological Noise

Take the whale noise as an example: the noise emitted by whales is about 15–45 Hz, and the duration is 1–20 s. Generally, there will be 50–100 repetitions, each interval being 1–20 s. There are some animal noise such as seals, but the impact of biological noise on the overall ambient noise in the Arctic is limited.

6. Ice Shore Noise

Ice shore noise is caused by the effects of ocean currents, sea breeze, and ice vortex on the coast. Noise levels in this area are generally higher. The main factors affecting the noise level are seawater conditions, water depth, and the size of the waves. T.C. Yang used sonar buoys in Greenland to observe ice shore noise and measured different shore ice conditions separately. The noise level is relatively high when the ice shore is compact and free of ice floes. In contrast, the noise level is relatively low when the shore has scattered floes.

7. Iceberg Melting Noise

There are a large number of tiny air bubbles in the water that forms icebergs. They are solidified in the ice due to the pressure. As the iceberg melts in the seawater, the gas in the ice suddenly released and made a sharp crack when the melting surface reaches the air bubbles. A sonar buoy is placed near the iceberg measuring the iceberg melting noise and found that the noise had a flat spectrum.

Propagation

The main features of the underwater propagation environment of Arctic Ocean were recognized: a

stable upward-refracting sound speed profile with an upper boundary of rough polar ice (Hutt 2012). Baggeroer reports that there are two positive spring layers in Arctic Ocean, halocline at about 40 ~ 50 m depth and syncline at 200 ~ 250 m depth, respectively.

When the source is upper the halocline, the sound is constantly reflected at the lower surface of the rough polar ice and can travel a long distance, which act like a surface duct. Acoustic waves with frequencies 15 ~ 30 Hz propagate best because of the rough polar ice scattering and energy conversion between flexural wave and polar ice. As the frequency increases, attenuation increases dramatically, because high-frequency components are scattered out by rough polar ice. Yet very low frequencies, below about 10 Hz, are not effectively trapped by the duct. Urlick summarized Arctic Ocean transmission loss shows that for frequencies less than about 100 Hz, propagation is approximately characterized by cylindrical spreading, which is an indication that the surface duct is an excellent waveguide for low frequencies (Urlick 1983). Characteristic transmission loss versus range based on numerous measurements is shown in Fig. 2.

When the source is near the spring layers, some grazing angle sound are trapped in another duct called “SOFAR” duct. In this duct, the sound can propagate without touching the bottom of the polar ice and the seabed so that travel a long range.

Reverberation

The sound waves emitted by the source impose the scatters and distribute the energy in all directions, i.e., result in scattering waves. The sum of the scattered waves returned to the receiving point constitutes the reverberation. The impact of polar ice variability is a major contributor in the reverberation of Arctic Ocean. The reverberation environment under Arctic ice is characterized by highly variable (and often large) scatter from the water-ice interface and low-volume scatter from the water column. The reverberation intensity is strongly correlated with the ice type and ice

Polar Acoustics, Fig. 2 Characteristic transmission loss versus range based on numerous measurements from the 1960s (Urick 1983)

roughness; sometimes the level of reverberation caused by Arctic ice is more than 40 dB higher than that of sea surface without sea ice (Marsh 1961).

J. R. Brown and A. R. Milne found that the scattering intensity of the covered sea ice region increases with the increase of the frequency and the grazing angle through the analysis of the observation data of two observation sites in the Arctic Ocean at different times of the year (Brown 1964). J. E. Burke and V. I. Twersky expressed the ice ridge as a semicylindrical elliptical rigid body and establish a Burke-Twersky model (Burke and Twersky 1966) that describes the reverberation under the ice in 1966, which is widely referenced and modified in following research.

In the 1990s, T. C. Yang and T. J. Hayward conducted research on low-frequency Arctic reverberation at different distances using CEAREX 89 test data from the Norwegian-Greenland Sea (Hayward and Yang 1993). For the short-range (less than 3 km) direct ice surface reflection reverberation, it is proved that the measured scattering intensity is consistent with the Burke-Twersky model law at the low frequency (24 ~ 105 Hz) when the grazing angle is less than

20°. For the mid-range (5 km ~ 20 km) mixing and reverberation under the ice surface and the seabed, the vertical array was used to separate the under-ice surface and the seafloor reverberation, and their degree of agreement with the model was verified respectively. For remote (no more than 200 km) very low frequency (10 Hz ~ 50 Hz) reverberation, an Arctic reverberation model based on a normal wave is established, and the model is verified by measurement data. It is pointed out that the effective reverberation intensity depends on the depth of the sound source in this case. Besides, the scope of the active sonar affected by reverberation can reach 200 km.

K. LePage and Schmidt find that Arctic reverberation has great spatial correlation, and half-wavelength correlation can reach 0.99 or more.

Polar Acoustics Technology

After the end of the Cold War, the interest in polar acoustics shifted from underwater surveillance to sensing of the Arctic Ocean and engineering application. Polar acoustics technology refers to the application of polar acoustics in the fields of

engineering implementation, environmental monitoring, shipping traffic, etc.

1. Acoustic Ice Thickness Measurement

According to different measurement principles, sea ice thickness measurement methods are mainly divided into direct measurement methods and indirect measurement methods. Indirect measurement methods are divided into physical detection methods and satellite remote-sensing methods.

Direct measurement methods mainly include sampling method of crushed ice, hole drilling method, and resistance heating method. The direct measurement method is to manually work directly on the ice, remove the ice sample, and measure the ice thickness directly. The method has advantages of high measurement accuracy and reliable data, but it is time-consuming and labor-consuming. It is only suitable for small areas and the thin ice thickness measurement.

Satellite remote-sensing uses satellite data for ice thickness measurement. This method can be used for a wide measurement range, but there are measurement errors at the intersection, and data reliability is poor.

Physical measurement methods include capacitance method, conductivity method, temperature method, electromagnetic induction method, ice-freezing degree method, on-site image measurement method, radar laser ranging method, and sonar measurement method. They can realize automatic monitoring of ice thickness for a long time without destroying the ice layer. In particular, in upward-looking sonar measurement method, the obtained ice thickness data has higher measurement accuracy and reliability and is less affected by external environmental factors.

Hudson and Wright tested the mooring fixation method in the Beaufort Sea, and in 1990s, Canadian Institute of Marine Fisheries Research develops Ice Profiling Sonar in order to measure the ice ridge thickness and underwater ice appearance of sea ice. Upward-looking sonar is also installed on a nuclear submarine and observes the thickness and morphological characteristics of ice ridges in the Arctic from beneath the ice

sheet. In 1996, ASL Corporation of Canada developed and commercialized the production of the top sonar. In 2008, it developed a new generation of model IPS5, whose ice thickness measurement accuracy in the vertical dimension reaches the order of centimeters, in the horizontal dimension, reaching the order of meters.

2. Acoustic Communication and Navigation

Acoustic communication is a useful method of transmitting information in the ocean, especially in the polar region covered with sea ice, as shown in Fig. 3. During the icing period, it is very difficult for vehicles to surface to communicate and obtain location information because of the uncertainty in the floating and thickness of sea ice. Furthermore, the harsh climate conditions in the Arctic are not suitable for long periods of activity. Acoustics solve this problem because the sound can travel a long distance. H. C. Song reported a successful acoustic information transmission over about 2720 km with a data rate of 2 bits/s (Song et al. 2014). More recently, Woods Hole Oceanographic Institution achieved underwater vehicle communication and navigation up to ranges of 70 ~ 90 km at a data rates 5 ~ 10 bit/s (Freitag et al. 2012).

3. Acoustic Thermometry

The idea of using low-frequency pulses transmitted over long distances to measure small changes in average ocean temperature was developed in the 1980s. This technique is called acoustic thermometry. The first attempt to carry out acoustic thermometry in the Arctic was the 1993 international experiment called Transarctic Acoustic Propagation (TAP). By examining the modal structure of the received signals, which is affected by bathymetry, ocean structures, and ice thickness, it was deduced that the Atlantic intermediate layer was intruding further into the Arctic Ocean (Hutt 2012).

A follow-on project to TAP, and also a US-Russian collaboration, was the Arctic Climate Observations Using Underwater Sound (ACOUS) experiment in 1998. Since the success of ocean

Polar Acoustics,

Fig. 3 Gliders and powered AUVs performing oceanographic work beneath the Arctic ice (Freitag et al. 2012)

acoustic thermometry and large-scale ice thickness measurement, the ACOBAR project has been established as a long-term tomography project by the Nansen Environmental and Remote Sensing Center; the ACOBAR experiment consists of a triangle of acoustic transceivers approximately 200 km from each other with a vertical receiver array in the center.

New Arctic Acoustics

With the global warming, the Arctic sea ice is decreasing year by year, which makes the acoustic environment of the Arctic Ocean different from that of the 20th century. Henrik Schmidt points that the changes in the environment of the Beaufort Sea severely deteriorated the tracking performance compared to previous deployments (Schmidt and Schneider 2016), and the reason was associated with a previously observed neutrally buoyant layer of warm Pacific water persistently spreading throughout the Beaufort Sea, which severely alters the acoustic environment with dramatic effects for both long- and short-

range acoustic sensing, communication, and navigation. All kinds of changes require us to reinvest to understand the current polar acoustics.

Polar Communications

Qiang Guo¹ and L. F. Chernogor²

¹College of Information and Communication Engineering, Harbin Engineering University, Harbin, China

²V. N. Karazin Kharkiv National University, Kharkiv, Ukraine

Introduction

In the twenty-first century, the Arctic and Antarctic regions, where the rich deposits of minerals have been found, are more and more

extensively being developed by humankind. For example, in the Arctic, gas deposits are estimated at 47.3 trillion m³, oil at 90 billion barrels, and gas condensate at 44 billion barrels. Their effective development is impossible without establishing reliable radio communication links with the Arctic and Antarctic regions.

According to the estimation by the European Space Agency, the stream of data in the Arctic region will increase tenfold over 2010–2020 (see Fig. 1). At the same time, the organization of communications in the Arctic region is hindered by the features of this region, the atmospheric and geospace structure, including the upper atmosphere, the ionosphere, and the magnetosphere. The Earth's magnetic field geometry is such that solar energetic particles penetrate into the polar regions, and the aurora, instabilities, geospace medium heating, a significant (by 1–3 orders of magnitude) increase in the electron density of the lower ionosphere, and other processes operate. All these events determine the instability of the atmosphere-ionosphere-magnetosphere communications links and result in considerable difficulties for organizing communications in the polar regions.

The instabilities in communications link significantly increase during major variations in space weather, the so-called geospace storms. As

Polar Communications, Fig. 1 Data rates required for the 75–90°N Arctic region (evaluated by European Space Agency)

is well-known, the geospace storm is comprised of the magnetic storm, the ionospheric storm, and the electric storm. The most prominent geospace storms in the polar regions occur when the ionospheric parameters and geoelectric fields vary by a factor of a few times to tens of times.

Conventional Communications

Communications in the polar regions provide radio waves in the frequency band from VLF (3–30 kHz) to VHF–UHF (30 MHz–3 GHz) when the near-Earth medium is used as a communications link.

VLF radio waves can propagate in the earth-ionosphere waveguide at distances, R , of 1,000–10,000 km. VLF communications are not disrupted even during the most severe geospace storms. The major drawback of VLF communication services is that the construction of large antenna systems with spatial sizes of about 100–1,000 m and high-power (of order of 1 MW) radio transmitters is needed and narrow (about 1 kHz) bandwidths are provided.

LF radio waves (30–300 kHz) can be reflected from the lower ionosphere over distances to a few thousands of kilometers. During geospace storms, the absorption of these radio waves drastically increases, and the link path length decreases. To provide stable communication services, large antenna systems with tenths of meters in height and high-power (~0.1–1 MW) transmitters are needed.

MF radio waves (300 kHz–3 MHz) can provide a ground-wave signal over distances of 100 km, and the signal reflected from the ionosphere can reach at distances of a few hundreds of km. The MF band has almost the same drawbacks than the LF band has.

HF radio waves (3–30 MHz) are particularly suitable for providing communication services in the polar regions. The radio waves in this wave band can travel as the ground wave at distances of no more than 50–100 km and as the ionospheric sky wave up to worldwide distances. When the distance reaches 4,000 kilometers, the HF radio wave can travel with a single reflection from

the ionosphere, while at greater distances, the HF wave can propagate in a waveguide with the walls which are usually made up by the ionospheric E and F layers. This waveguide is termed the interlayer waveguide, and the HF attenuation in this waveguide is significantly lower than on multi-hop links. The HF radio waves are mostly subjected to the variations in space weather.

The optimal frequency is given by

$$f_{opt} \approx 0.85 f_{MUF},$$

where f_{MUF} is the maximum usable frequency. This frequency does not exceeds $3f_{pmax}$, where

$$f_{pmax} = \frac{1}{2\pi} \sqrt{\frac{e^2 N_{max}}{\epsilon_0 m}}.$$

Here f_{pmax} is the plasma frequency, e is the electron charge, m is the electron mass, ϵ_0 is the permittivity of free space, and N_{max} is the F -region peak density. Under quiet conditions, the value of N_{max} is equal to approximately 10^{12} m^{-3} in the daytime and about $(2-3) \times 10^{11} \text{ m}^{-3}$ at nighttime, resulting in the diurnal variation of $f_{pmax} \approx 9-4 \text{ MHz}$ and of $f_{opt} \approx 23-10 \text{ MHz}$, respectively. During a positive ionospheric storm, the N_{max} values can increase by a factor of 2–2.5, resulting in $f_{opt} \approx 35-15 \text{ MHz}$. During a negative ionospheric storm, the f_{pmax} decreases by a factor of 3–4, resulting in $f_{opt} \approx 7-3 \text{ MHz}$. It should be noted that during ionospheric storms, the ionospheric D region electron density (50–90 km altitude) may be increased by a factor of 10–100 and the ionospheric E region electron density by a factor of 2–3. The integral absorption coefficient, K , may be increase by a factor of the same magnitude as given by

$$K = \frac{2\pi f}{c} \int_s \kappa ds,$$

where f is the radio wave frequency, c is the speed of light, ds is the radio wave path, s is the element, and κ is the absorption coefficient, given by

$$\kappa = \pi \frac{f_p^2 \nu}{f(4\pi^2 f^2 + \nu^2)}.$$

Here f_p is the plasma frequency, and ν is the collision frequency. Usually, $4\pi f^2 \gg \nu^2$ and

$$\kappa \approx \frac{f_p^2 \nu}{4\pi f^3}.$$

It is important that $\kappa \sim N\nu/f^3$ and $K \sim f^{-2}$.

The transmitter and receiver antennas are small and relatively simple, and the required transmitter powers are small (~ 1 – 10 kW) as well. This is the first advantage of HF radio wave service. The other advantage of HF service is that it permits two-way communications at large distances of $1,000$ – $10,000$ km.

The major drawback of the HF service is that it is profoundly affected by the state of the ionosphere and the space weather, and consequently, the optimal operating frequency should be adjusted almost continuously during the day and during ionospheric storms. During major storms, the HF service can be lost at all.

At frequencies greater than 30 MHz, the communications are possible within the straight line-of-sight horizon. The distance to the radio horizon does not exceeds the value given by

$$R_{\max} \approx \sqrt{2R_E} \left(\sqrt{h_1} + \sqrt{h_2} \right),$$

where $R_E \approx 6,400$ km is the Earth's radius, h_1 is the transmitter antenna height, and h_2 is the receive antenna height. For example, when $h_1 = h_2 = 9$ m, we find that $R_{\max} \approx 21$ km. For a service with an aircraft ($h_2 \approx 10$ km), $R_{\max} \approx 358$ km, and with a low-Earth-orbit satellite ($h_2 \approx 400$ km), $R_{\max} \approx 2,260$ km.

The communications with frequencies greater than 30 MHz are relatively weakly dependent on the state of the ionosphere and space weather, because the relative refractive index of the ionospheric plasma is given by

$$n = \left(1 - \frac{f_p^2}{f^2} \right)^{1/2},$$

and when $f^2 \gg f_p^2$, it differs from unity slightly. Furthermore, the absorption coefficient $\kappa \sim f^{-3}$ rapidly decreases with increasing radio wave frequency.

Communications Based on Radio Wave Scattering

The VHF (30 – 300 MHz) radio waves can be scattered by the irregularities of the refractive index in the troposphere and the ionosphere, as well as by meteor trails. Consider them in detail.

Tropospheric Scattering. Tropospheric scattering occurs from the irregularities in the refractive index, Δn , of the troposphere. Usually, the root-mean-square (RMS) refractive index fluctuations $\sigma_n \approx 10^{-4}$ – 10^{-3} , and they do not depend on frequency. Since $\sigma_n \ll 1$, the power of the signal scattered by the tropospheric irregularities is very small. To utilize this effect for radio communication, large aperture (~ 10 m) antennas and high-power (~ 10 – 100 kW) transmitters are needed. Such a service provides radio communication over ~ 100 – $1,000$ km, while this path incurs 50 – 120 dB of loss at 100 MHz. The maximum propagation distance can be estimated from the following formula:

$$R_{\max} = 2\sqrt{2R_E h_t},$$

where h_t is the altitude of tropospheric irregularities. For example, for $h_t = 10$ – 15 km, we have $R_{\max} \approx 720$ – 880 km.

The communication based on the tropospheric scattering suffers from seasonal and climatic factors. The major drawback to this kind of service is multipath interference caused by signal fading. As a result, the bandwidth of such a communications channel is limited.

Ionospheric Scattering. Over-the-horizon communications, usually at VHF, occur due to scattering by irregularities in the ionospheric D region. The root-mean-square electron density fluctuations are given by $\widetilde{\sigma_N} = \left((\Delta N/N)^2 \right)^{1/2} \approx 10^{-2} - 3 \cdot 10^{-2}$, and the RMS refractive index fluctuations are given by

$$\sigma_n \approx \frac{1}{2} \frac{f_p^2}{f^2} \widetilde{\sigma}_N.$$

It is important that the scattered power is proportional to σ_n^2 , i.e., $\left(f_p^4 \widetilde{\sigma}_N^2\right) / f^4$. The signal power rapidly decreases with increasing frequency, for example, the signal power decreases by a factor of 100 when the frequency increases about 3 times.

In the range of 30–70 MHz frequency, the attenuation varies from –90 dB to –120 dB. The maximum propagation distance can be estimated from the following relation:

$$R_{\max} = 2\sqrt{2R_E h_i},$$

where h_i is the altitude of ionospheric irregularities. For example, $h_i \approx 90$ km yields $R_{\max} \approx 2,160$ km, and the frequency band does not exceed 6 kHz.

Electron density irregularities also occur in the ionospheric E and F regions, where they are elongated along the geomagnetic field lines. Such irregularities provide aspect angle scattering and the maximum propagation distance of $R_{\max} \approx 4,000$ km.

Meteor Communication. Meteor communication systems operate in an intermittent mode and utilize only single meteor ionization trails that appear sporadically (not meteor showers or streams). The number of such meteors entering the Earth's atmosphere per day is estimated to be $n_0 \approx 10^{11}$, while their flux $n \approx 2 \times 10^{-3} \text{ km}^{-2} \text{ s}^{-1}$. Small meteors “burn up” in the height range of $h_m \approx 80$ –120 km and form an ionization trail with 10^{10} – 10^{18} m^{-1} electron density per unit of line length. The initial density per unit of volume is $N \approx 10^{11}$ – 10^{18} m^{-3} . The trails persist for ~0.1–10 s. The time of the SNR exceeding the threshold accounts for only 1–10% of the total running time of the system. Scattering from the meteor trails depends on the aspect angle. The maximum range of the meteor channel is 2,000–2,200 km, the channel losses attain 170 dB, and the channel has an instantaneous data rate of ~100–1,000 bit/s. The meteor channels have moderate information data rates

and require moderate transmitter power (~1–10 kW) and relatively simple antennas with an antenna gain of 15–20 dB. The major drawback of meteor channels is the complexity of the system design. The International Telecommunication Union Recommendation ITU-R F.1113, radio systems employing meteor-burst propagation, at https://www.itu.int/dms_pubrec/itu-r/rec/f/R-REC-F.1113-0-199409-1!!PDF-E.pdf describes the construction of two such systems at a realistic commercial cost.

Terrestrial Relay Links

These services can be provided by both conventional and new repeaters.

Conventional Repeaters. The system requires ~1–10 m antennas, 20–30 dB antenna gains, and ~1–10 kW transmitters. The maximum propagation distance is given by the relation:

$$R_{\max} = 2\sqrt{2R_E h_r},$$

where h_r is the relay station height. For example, substituting $h_r = 10$ m, we have $R_{\max} \approx 23$ km. The small values of $R_{\max}$ are the major drawback to the conventional repeaters.

New Repeaters. Airships provide a relay station with the height of $h_r \sim 1$ km, and stratosphere balloons stable in space can attain heights of $h_r \approx 20$ –25 km. These platforms can support communications at ranges of 226 km and 1,010–1,130 km, respectively.

Cable Links

The Russian Optical Trans-Arctic Cable System, ROTACS, (<http://www.polarnetproject.net/>) project intends to connect the UK, Russia, China, and Japan with optical cable. In the first stage, six pairs of optical fibers are planned to be laid out. The first phase of work is estimated at about \$1 billion.

Countries in the Arctic region advanced the Arctic Fibre project to connect the UK, Ireland, Canada, the USA, and Japan.

Canada has built Ivaluk Network to serve the needs of Northern Canadians with an optical cable loop of 8,000 km.

Arctic Communications Satellite Links

Satellites are practical for providing communications in the Arctic regions. Moreover, this kind of communication is preferable and advanced. The satellites used for these conditions include geostationary and low-Earth-orbit satellites, as well as satellites in highly elliptical orbit. Consider these opportunities in more detail.

Geostationary Satellites. In Alaska and the USA, high-quality video and broadband services are delivered by Intelsat, Telesat, and other providers of communication satellite service, when the satellites are at an angle of 9° over the horizon.

In Arctic Canada, broadband services and Internet connections are provided by the Telesat

operator via the AnikF1R, AnikF2R, and AnikF3R satellites.

In Norway, communications and broadcasts are delivered via the Thor satellite and, in Russia, via the Express satellite.

The major drawback of communications via geostationary satellites is that they become unstable at low angles of the satellites over the horizon.

Satellites in Highly Elliptical Orbits (HEO). Such a kind of project does not exist yet. Communications through these satellites lack the advantage that geostationary satellites have. Satellites on high elliptical orbit will be repeatedly immersed in the radiation belt, which can shorten the life span of spacecraft electronics components.

Low-Earth-Orbit (LEO) Satellites. The *Iridium NEXT* constellation operates in the L-band at 2.4–132 kbps data rates (Table 1).

Gonets System (Russia) is composed of 12 satellites in 1,400 km orbit at 82.5° orbital inclination. The data rate is 2.4–64 kbps, and the frequency used 200–400 MHz.

When completed, the *Kosmonet* satellite project will consist of 48 satellites. The total cost of this project is \$0.3 billion.

Polar Communications, Table 1 An overview of Iridium services. (Data from Iridium homepage (<http://www.iridium.com>))

Service	Iridium	Iridium NEXT
Voice	2.4 kbps	2.4 kbps
Circuit switched data	2.4 kbps	9.6–64 kbps
Short burst data	low	On demand
OpenPort	132 kbps	128–512 kbps
OpenPort aero	132 kbps	128–512 kbps
L-band high speed	N/A	512 kbps up–1.5 Mbps down
Broadcast	N/A	64 Mbps

New Missions Toward the Arctic

New missions are the following: (1) Antarctic Broadband (ABB); (2) Arctic Region Communications Small Satellites (ARCSS); (3) Polar Communications and Weather (PCW); (4) Arktika (A); and (5) CASSIOPE/Cascade (CC) (Table 2).

Polar Communications, Table 2 Proposed satellite communication systems (Birkeland 2014)

System	Frequency band	Capacity	Con't coverage	Arctic coverage
ABB	Ka	TBD	No	?
ARCS	S, X, UHF	3 Mbps	No	Yes
PCW	TBD, UHF	TBD	No?	Yes
A		Mobile	Maybe	Yes
CC		Gbit	No	Yes
Telenor HEO		Broadband	Yes	Yes

► Winterization of Polar Engineering

Polar Materials

Zhongwu Zhang and Ye Cui
College of Materials Science and Chemical Engineering, Harbin Engineering University,
Harbin, China

Definition

Polar materials always refer to materials used in cold climate zones. Polar materials should

withstand the effect of the polar region climate without sacrificing other performance properties. Reliability, durability, trouble-free operation, and reparability are the requirements for the application of polar materials under polar region conditions. The exploration of the polar regions is largely determined by the availability of materials that are necessary to create technical devices and facilities and can ensure comfort for people who stay and work in severe climatic conditions.

Scientific and Engineering Fundamentals

Service Environment of Polar Materials

Polar Regions

The polar regions are the regions of the planet that surround its geographical poles (the North and South Poles), lying within the polar circles. These high latitude regions are dominated by polar ice caps: the northern resting on the Arctic Ocean and the southern on the continent of Antarctica. These regions include ice and marine sites with islands and straits and a part of the coast.

The polar regions are the last unspoiled natural treasures with huge reserves of minerals and resource on earth. In recent years, polar regions, especially Arctic region, have become regions interesting to the global community due to transportation, geopolitical, military, and raw material-related reasons. Today, only a small portion of the polar regions can be developed due to the huge infrastructure costs, the required reliable equipment, and the limitations of polar materials. The ability to explore and develop polar regions depends on the materials necessary to create technical installations and facilities for severe climatic conditions in the polar regions. Developing polar materials has become one of the keys to develop polar regions and utilize the polar region resources (Buznik et al. 2018b).

The characteristic features of the polar region are extreme natural and climatic conditions such as long-term low temperatures, significant annual temperature gradients (from $-60\text{ }^{\circ}\text{C}$ to $40\text{ }^{\circ}\text{C}$),

strong winds, high humidity, glaciation and snow buildup, the presence of ice caps covering in the seas, a high solar radiation during the polar day, and a low environmental stability. The simultaneous effects of all the factors mentioned above make the polar climate especially severe and the application of polar materials especially complex and strict.

Another important characteristic feature is that the polar region environment is sensitive to anthropogenic impacts. Therefore, industrial centers and densely populated settlements are far from the polar regions; the production and transport infrastructure are weak in polar regions; people, raw materials, and equipment need to be brought from the warm continents. Even small accident in polar regions can have serious consequences for humans and the polar region environment. Hence, there are strict requirements for polar materials: polar materials should retain their functional properties as long as possible.

Glaciations and snow buildup lead to additional mechanical loads. Sea water can cause severe corrosion. Moisture provides another negative climatic impact, which initiates metal corrosion and degrades the properties and structure of polymeric composites. Under the polar region conditions, this phenomenon is aggravated by negative temperatures and repeated transitions through the melting point of ice, which accelerates corrosion. The most important is that the ships used in polar regions and the related offshore structures may face risks associated with accidents such as iceberg collisions. Obviously, high-quality polar materials should withstand all the severe climate mentioned above, not solely individually or some of them.

Characteristic Features of Polar Materials

Cold is the main climatic characteristic feature of the polar regions. Long-term service in polar region low temperatures is the biggest challenge for polar materials. However, the impact of cold is not limited to geographical positions; one can identify many of the more severe cold continental areas. So polar materials always refer to materials used in cold climate zones. And polar materials should withstand the effect of the polar region

climate without sacrificing other performance properties. The important requirements on polar material are their reliability, durability, trouble-free operation, and reparability under field conditions. Therefore, structures used in polar regions are more rigorous, more precise, and more discreet than structures used in warmer regions.

Development History of Polar Materials

At the initial stages of the exploration and research of polar regions, natural materials (wood, wool, leather, coal, ice, and so on) were the main materials for the production of vessel, clothes, household, and building materials. However, the properties of these natural materials are very limited, which is not enough to further develop and explore the polar regions. Hence, from the nineteenth century, anthropogenic materials have replaced natural materials to become the most used materials for producing transport, household, and products for everyday life in polar regions. Recently, the performance requirements for polar materials increase rapidly with the requirements for exploring, utilizing, and developing polar regions. Today, there are two major ways to develop polar materials. The first is the specialized development of materials, and the second is adaptation of the existing materials, giving them additional performance for effective use in the polar regions (Buznik et al. 2017, 2018a, b).

Polar Steels

Steel is the main modern construction material. However, it is the most vulnerable material in the polar regions; the vessels used in polar region waterways and the related offshore structures are exposed to risks of brittle fractures due to accidents such as collisions with icebergs. The brittle fracture of steel in polar environments has caused many serious accidents. Moreover, the steels always manifest frost fracture under low temperatures, leading to the destruction of technical facilities. This phenomenon can be attributed to many factors: external impacts, traits of crystalline phases of iron, the microstructures, the presence of inclusions and textures in steels, etc. (Sychev et al. 2017).

Improving the toughness of steels under low-temperature conditions and preventing the occurrence of brittle fracture have become the main challenges for conventional steels used as polar materials. At present, the special alloying and thermomechanical processing have been used to solve the technical problem for alleviating the brittle fracture and frost cracking and meet the operation requirements in polar regions. The newly developed steels have already been tested in building pipelines, vessels, and the offshore oil platform. In addition, searches have conducted for techniques that would ensure an optimal combination of functional and economic indicators of cold-resistant steels. The properties of steels should be examined carefully and extensively before choosing the certain steel grade.

Carbon Steels Carbon steel is the most commonly used structural material in the world. They are cost-efficient in most applications and have good stiffness, high strength, high durability, and recyclability. Since the ductile-brittle transition temperature of carbon steel is generally between room temperature and -40°C , it must be strictly required for steel grade selection, manufacture, assembly, and inspection, when carbon steel is used in polar regions.

In general, the polar carbon steels can be divided into four different groups as normal strength steel, high strength steel, extra high strength steel, and ultrahigh strength steel.

The normal strength steels (e.g., P215NL pipe steel and grade E steel and steel EW steel certified by classification societies) have yield strengths up to 235 MPa, which are used in pipelines, offshore, and inland applications. For example, P215NL and grade E steel are tough at the temperature of -40°C , which suggests that these steels can be used in few polar areas. Grade EW steel has the transverse impact test energy up to 40 J at temperature of -40°C , and its weldability was improved. These suggest that it is more suitable for welding applications than the other two kinds of steel.

The high strength steels (e.g., pipeline steels L245-L390, 11MnNi5-3, 13MnNi6-3, 12Ni14, X12Ni5) have yield strengths exceeding

235 MPa up to 400 MPa. Their ductile-brittle transition temperatures reach -40°C or below. These steels are used in offshore pipelines, offshore fixed applications, and offshore vessels. 11MnNi5-3 and 13MnNi6-3 could work as offshore pipeline steel at -60°C . The Charpy-V impact energy 12Ni14 and X12Ni5 reach 40 J at -100°C and -120°C , respectively. Pipeline steel L320 and L360 could operate about 30 years as gas main.

The extra strength steels (e.g., E500, F420-690, X10Ni9 and 26CrMo4-2) have yield strength exceeding 400 MPa up to 700 MPa, and their transition temperatures also reach -40°C or below. Many steels in this group were used in nonredundant structures in polar regions around -60°C (Pavel et al. 2016).

The ultrahigh strength steels (e.g., L830, S890QL, S890QL1, and S960QL) have yield strength exceeding 700 MPa, and their transition temperatures reach -40°C or below. The pipeline steel L830 or X120 is standardized with impact energy of above 250 J at -30°C .

Polar Alloy Steels Polar alloy steels were also developed for offshore or general inland structural application. Steel 09Г2С (09Mn2Si), steel 10Г2, steel 10Г2С1, and steel 16ГС were developed for operating at pole region environments with temperature as low as -70°C in Russia (Panin et al. 2017). For example, steel 14Г2АФ is a ferrite-pearlite-based high-strength alloy steel with low corrosion resistance. It has yield strength and fracture toughness parameter of Charpy U impact of 540 MPa and 110 J/cm^2 at -60°C , respectively. Therefore it is recommended for manufacturing vessels and machinery operated at the temperature range of -50°C to 400°C .

High-strength low-alloy steels have good weldability and high yield strength (even over 1000 MPa). For example, steel 18Г2Ф is kind of high-strength low-alloy steel developed by Russian. Its yield strength and fracture toughness parameter of Charpy U impact test could reach 440 MPa and 29 J/cm^2 at -70°C , respectively. Therefore, it can work at variable temperatures ranging from -60°C to 450°C .

Polar Stainless Steels Polar stainless steels are typically used in applications where good corrosion resistance and low-temperature mechanical properties are obligatory. For example, they are used in cargo tanks, storage tanks, shafts, and pressure vessels, especially the pipelines. Polar stainless steels are often categorized to four different main groups: austenitic, ferritic, austenitic-ferritic (duplex), and martensitic polar stainless steels. Now, several stainless steels were developed in structures and pipes at low temperatures of polar regions. For example, AISI 304, 304L, 316, 316L, 321, and 347 can be used in offshore applications.

Polar Steel Welding The welding of polar steel is the most important factor to determine whether the steels can be used in polar region as modern structures, vessels, pipelines, and offshore (Pavel et al. 2018). Modern structures and vessels require the thick-welded steel plates with yield strengths of 690 MPa or more and exceeding plasticity and toughness. In the recent years, some high-strength cold-resistant steels with high plasticity and satisfactory weldability were developed for using as welded parts in the polar region conditions of -20°C . However, some irreversible structural changes are likely to occur due to the influence of the welding thermal cycle during the welding process, which reduces the cold resistance of the welding heat-affected zone in the heat-affected zone. Therefore, the welding techniques become a key problem for using these high-strength cold-resistant steels in polar regions. Research shows that reduction of the carbon content and alloying level could increase the mechanical properties of welding joint and lower the HAZ toughness, which implies that the development of high-strength low-alloy steel with good weldability and low-temperature mechanical properties may be an important way to obtain high-performance polar steels in the future.

Testing Methods of Polar Steels Steel and welded constructions can rupture rapidly under effect of low temperatures of polar regions. This phenomenon is due to the existence of the ductile-brittle transition temperature below which the

steels are brittle. The welding defects and fatigue cracks can occur unexpectedly in the stress-concentrated areas under low loads in polar regions.

Therefore, good toughness (impact toughness, fracture toughness, crack arrest toughness, and so on) is a desirable character for polar steels used as structural material. Several test methods were developed to analyze the toughness of metals; most common methods are Charpy-V impact, crack tip opening displacement (CTOD) or crack tip opening angle (CTOA), and Nil-ductility temperature (NDT) or drop-weight test (DT) or drop weight tear test (DWTT). Recently, temperature gradient type ESSO test and temperature gradient type double-tension test are developed for evaluating the brittle crack arrest toughness (Shimada et al. 2017).

By far the most common toughness test method is the Charpy-V impact test. As a traditional toughness test method, the Charpy-V impact test is easy to operate and clearly shows the toughness of traditional materials. The Charpy-V impact test uses a pendulum with certain weight and speed to impact a standard sized sample. After the collision, the energy absorbed by the sample is recorded to obtain the notch toughness of the test material.

The CTOD test was performed by placing the sample in a three-point bending machine and measuring the opening of the crack after applying the load. It obtains the stress intensity factor at the crack tip by calculating the open displacement near the crack tip and using the displacement extrapolation interpolation method. It has become more important in recent years for the CTOD test to have the ability to use a full-size specimen with a crack under the stress corresponding to the load actually used.

The DWTT is a method for evaluating the metallurgical quality and brittle fracture of test sample. It measures the impact energy absorbed in the test sample and observes the characteristics of metallurgical defects, fracture properties, and morphology. It can be used to compare welded parts and test “Nil-ductility temperature.” The “Nil-ductility temperature” is obtained by testing multiple samples at different

gradually decreasing temperatures until the specimen is broken.

Nonferrous Metallic Materials

Beside steels, many other metallic materials are also used in polar regions (Buznik et al. 2018a, b; Buznik and Kablov 2017). Among them, aluminum alloys are widely used in offshore structures for their lightweight and good corrosion resistance even in presence of sea water, such as deck structures. The other advantage of aluminum alloys used in polar region is that they are not suffered from the ductile-brittle transition at low temperature. In general, 5xxx and 6xxx series aluminum alloy, with different tempers, are classified for offshore use. 5xxx series products are valid in forms of sheet, strip, and plate and 6xxx series for extruded products. Other metals and alloys, such as titanium alloys, manganese alloys, and copper-based alloys, were also used for constructions and facilities and structural frames in polar regions.

High Molecular Compounds

The great interest in the applications of high molecular compounds in polar region is due to their great chemical diversity and broad spectrum as construction, functional, and auxiliary materials. High molecular materials, including oligomers, thermoplastics, thermosets, elastomers, etc., have been widely applied to produce products used in polar regions, such as glues, sealants, coatings, fillers, anti-icing coatings, hydrophobic polymer and oligomer materials, frost- and fire-resistant rubbers, weatherproofs, hydrophobic, and tribological coatings. High molecular materials are also used for low-temperature oil- and gasoline-resistant elastomers, ultrahigh molecular weight polyethylene with a high toughness and crack resistance, and high-performance radiation-modified polytetrafluoroethylene and polymer electrolytes. Low temperatures are harmful for high molecular compounds: polymers and rubbers vitrify, crystallize, and lose their serviceability and destruction (Petrova et al. 2016). Various fillers are being sought actively to increase the cold resistance of materials within acceptable cost.

Ceramics Materials

Ceramics materials, including glasses and cements, have been used to produce the heat-resistant glasses (used for alarm systems and navigation systems of rescue vessels), various coatings, porous fire-resistant heat-insulating materials, electrode materials for chemical current supply sources operating at low temperatures, and radiation-resistant ceramic materials.

Composites

Metallic, ceramic, and polymeric composite materials have been used to produce structural frames, composite protector hydro- and ice-phobic coatings, high-strength hydrophobic CMs with a low coefficient of friction, heat and noise insulation, and composite paint-and-lacquer systems.

Other Materials

In addition to the above materials, natural materials were also developed and used in polar regions (Schulson 2015), such as ice, liquid fuels and low-temperature lubricants, electrochromic and heatproof coatings for glasses, frost-resistant textile materials, etc.

Polar Merchant Ship

► Polar Merchant Vessel

Polar Merchant Vessel

Shaocheng Di
College of Shipbuilding Engineering, Harbin
Engineering University, Harbin, China

Synonyms

Polar merchant ship; Polar merchantman; Polar trading vessel

Definition

The polar merchant vessel is a boat or ship sailing in the polar region in order to transporting cargo or

carrying passengers for hire. This excludes pleasure craft that do not carry passengers for hire. Warships are also excluded. As to the unique natural environment of the polar region, some icebreakers are also belonged to this region.

The Reason for the Emergence of Polar Merchant Ships

With the continuous exploration of the polar region, the abundant resources of the polar regions are gradually known by human beings. The arctic alone holds 30% of the world's undiscovered gas reserves and 13% of the world's undiscovered oil reserves, according to resource exploration (Gautier et al. 2009). Besides, the arctic is rich in beryllium, indium, niobium, platinum, graphite, rare earth and other minerals. In addition, by using the arctic route, the distance between East Asia, Europe, and North America will be greatly shortened, as shown in Fig. 1. For example, the distance from Rotterdam to Yokohama via the Suez Canal is 20,742.40 km. If it goes through the northeast channel, its distance is only 12,038 km, which is reduced by 40%. Likewise, from Seattle to Rotterdam, the northwest passage is 25% shorter than the panama canal route (Borgerson 2008).

Considering the cost of canals, fuel, and so on, a single trip would save nearly a million dollars in transportation costs. More and more people's yearning for polar scenery has also promoted the development of polar mail ship.

Polar Regulations and Influence of Polar Merchant Vessel

It is we all known that the geographical environment of the polar sea is different from that of other sea. Cold water, lots of floating ice, and icebergs make it extremely difficult for polar merchant vessel. Therefore, polar ships often need some unique design and navigation routes.

In 2006 IACS has issued a unified requirement for polar Marine, *Requirements Concerning Polar Class*, which is formulated by the nation

Polar Merchant Vessel, Fig. 1 Illustrations for Northwest and current routes (a) from Rotterdam to Seattle; (b) from Rotterdam to Yokohama (Borgerson 2008)

classification societies jointly. The requirement for the design and construction of the polar ships provides a unified standard on the hull structure, machinery, etc. Using additional signs, PC1 ~PC7, to show polar classification (IACS 2011). This requirement should be used by major classification societies in their classification codes as a basis of classification for polar ships. However, this requirement only provides indicative requirements, which cannot be used as a guide document for polar ship design. Therefore, the implementation and verification levels of the requirements vary from country to country.

International maritime organization (IMO) issued a guide *International Code for Ships Operating in Polar Waters* in December 2002 (IMO 2013). The main contents include: hull structure, subdivision, stability, electrical equipment, fire safety, rescue device, emergency equipment, environmental protection, and so on. Indeed, it is suitable for vessels in the arctic waters. On the base of the code, ships sailing in Antarctic waters are also supplemented. The *Polar Code* was adopted in 2014 as a mandatory rule for polar

sailing ships, which took effect on January 1, 2017.

In terms of the typical design of ice ships, the ship's plate and deck which is closed to the outside should avoid cold brittle damage at low temperature. In order to restraining the expansion due to ballast water translating to fresh water ice, ballast tank and some similar structures in polar ship should have the appropriate excess volume (10%). Especially, the piping system (including the air permeability pipe) serving the tank should prevent being frozen.

Polar Merchant Ship Categories

Polar merchant vessels can be divided into polar bulk carrier, polar container ship, polar tanker, and polar cruise ship. Based on the special environment of the polar regions, polar tanker accounts for a significant proportion of polar ship. Moreover, Polar cruise vessels are mainly used for sightseeing.

Polar Bulk Carrier

Bulker carrier is a merchant ship specially designed to transport unpackaged bulk cargo, such as grains, coal, ore, and cement, in its cargo holds. Today’s bulk carriers are specially designed to maximize capacity, safety, efficiency, and durability. Polar bulk carrier should pay attention to the cold resistance of their cargo and their own thermal insulation.

Yong Sheng

“Yong Sheng” is a polar bulk carrier of Chinese COSCO shipping company, which is shown in Fig. 2. It started from Tai Cang port in 2013 and reached Rotterdam, the Netherlands, via the arctic route. It is the beginning of the arctic voyages of Chinese merchant ships. From then on, Yong Sheng crossed the arctic route four times from 2014 to 2017 and arrived in Europe from China. During this period, several vessels belonged to Chinese COSCO shipping company undertook more than ten commercial voyages.

Main Dimension of Yong Sheng Ship

Classification	LR, +100 A1, Ice Class 1A Strengthened for heavy cargoes Equipped with container securing arrangement
GRT/NRT	14,357/6,985 mt
Deadweight (summer)	19,561 mt

Max draft (summer)	8.42 m
LOA	159.99 m
Breadth	23.70 m
Depth to main deck	11.95 m
Height above keel	41.10 m
Max speed	14.80 kn

Polar Container Ship

Container ships are cargo ships that carry all of their loads in truck-size intermodal containers, professionally called containerization. They are a common means of commercial intermodal freight transport and now carry most seagoing nonbulk cargo. So far, polar container ships have not been the mainstream of polar merchant Vessel. In other words, polar container ships do not have enough travel times as much as polar oil tankers and polar bulk carriers. Zapolyarniy, a polar container ship, sailed between Shanghai, China, and Dudinka, Russia, sailing through parts of the northeast passage.

Polar Tanker

A tanker is a ship designed to transport or store liquids or gases in bulk. Due to the abundant natural gas and oil resources in the polar and circumpolar regions, polar tanker accounts for the largest proportion of polar merchant vessel.

Polar Merchant Vessel, Fig. 2 Yong Sheng ship (<http://www.coscol.com.cn>)

UIKKU

In 1997, UIKKU became the first merchant ship under non-Soviet flag to navigate the entire Northern Sea Route, which is shown in Fig. 3. In the following year, she took part in Arctic Demonstration and Exploratory Voyage (ARCDEV), a research project funded by the European Union to determine the feasibility of year-around navigation in the Northern Sea Route (Transport Research Knowledge Center 2003). UIKKU accompanied by a Russian nuclear-powered icebreaker NS Rossiya to open the way and a research icebreaker Kapitan Dranitsyn to provide facilities to 70 researchers from different countries carried a cargo of gas condensate from Ob river estuary to Europe.

General Characteristics (Russian Maritime Register of Shipping)

Tonnage:	11,290 GT 4,937 NT 16,038 DWT
Displacement:	22,654 tons
Length:	164.40 m (539.37 ft) (overall)
Beam:	22.22 m (72.90 ft)
Draught:	9.55 m (31.33 ft)
Depth:	12.00 m (39.37 ft)
Ice class:	1A Super RMRS UL
Installed power:	2 × Wärtsilä Vasa 12V32E (2 × 4,920 kW)

1 × Wärtsilä Vasa 12V22D-HF (1950 kW)

Propulsion:	Diesel electric propulsion 11.4 MW Azipod unit
Speed:	17 knots (31 km/h; 20 mph)
Capacity:	8 cargo tanks, 16,215 m ³ (98%)

Polar Targeting Design

In order to adapt to arctic navigation, people have made a series of changes to UIKKU. Designers have given UIKKU so much power that tankers usually only need to keep one of the two engines working. In addition, hull structures being similar to icebreakers are given to UIKKU. To reduce the friction between the hull and the ice, the ships were also equipped with an air bubbling system (Nathan et al. 1996). Besides, according to IMCO’s nonmandatory requirements, the hull was designed with double hulls to avoid grounding (Gallin et al. 1981).

New Polar Tanker – Double Acting Shuttle Tanker

A shuttle tanker is a ship designed for oil transport from an off-shore oil field as an alternative to constructing oil pipelines. Both double acting shuttle tanker’s bow and her stern can break the ice continuously. It implements that the sailing bow forward is suitable for open water, and the sailing stern forward is suitable for ice. It settles an

Polar Merchant Vessel,

Fig. 3 Towing of tanker UIKKU By icebreaker (From Final public report of the ARCDEV project)

economic problem which results from the difference of sailing environment.

We should be clear that making the ice broken is not a simply collision when the double acting shuttle tanker sails stern forward, but using full-revolving propulsor breaks the ice. In this way, we can collapse the ice and at the same time also rotate the ship stern, broaden the channel. However, it is a slow process.

Timofey Guzhenko

She is completed at 24 February 2009, as shown in Fig. 4. Her sister ship Vasily Dinkov delivered 2007 is the first double acting shuttle tanker.

General Characteristics

Type: Shuttle tanker

Tonnage: 49,597 GT 21,075 NT 72,722 DWT

Displacement: 93,515 tons

Length: 257 m (843 ft)

Beam: 34 m (112 ft)

Draught: 14.2 m (47 ft)

Depth: 21 m (69 ft)

Ice class: RMRS Arc6

Installed power: $2 \times$ Wärtsilä 16V38B

($2 \times 11,600$ kW)

Wärtsilä 6L38B (4,350 kW)

Propulsion: Diesel-electric two ABB Azipod

units (2×10 MW)

Speed: 15.7 knots (29.1 km/h; 18.1 mph)

Polar LNG Carrier

An LNG carrier is a tank ship designed for transporting liquefied natural gas. Likewise, the polar LNG tanker is a kind of polar tanker. Because of the polar region and its environs owning huge gas reserves, LNG ship is becoming a super star of polar merchant ships with the launching of the Russia Yamal project.

Christophe De Margerie

Christophe De Margerie, as shown in Fig. 5, made its maiden voyage in mid-august 2017. Its owner is Russia's shipping company, Sovcomflot. In one voyage, she can carry $172,600 \text{ m}^3$ of LNG.

The ship is 299 m long, 50 m wide and has a draft of 8.42 m. The ship loaded LNG from Hammerfest Norway on August 6, in the absence of icebreaker's escort, going through the north pole route, across the Bering strait, arriving in South Korea on August 17th. The voyage set a new record on the shortest route across the arctic. In addition, 14 polar LNG carriers will be built for Russia's Yamal LNG project. This will help customers in Japan, South Korea, and China to speed up cargo turnover and help develop polar route in the arctic.

As far as we know, her ice-class was assigned as Arc7, the highest ice class among existing polar LNG carrier. The ship is able to go through ice area independently until the ice is over 2.1 m thick. It is attribute to her bow and stern are

Polar Merchant Vessel,

Polar Merchant Vessel,
Fig. 5 Polar LNG carrier
Christophe De Margerie
(<http://www.sovcomflot.ru/>)

covered with 70 mm steel and can withstand -52°C . Furthermore, strong motivation also guarantees that she can travel in the ice area. The total power of this vessel’s propulsion system is 45 MW. Compared to the world’s first nuclear-powered ice-breaker, Lenin, owning 32.4 MW propulsion system, only accounts for around two thirds of Christophe De Margerie’s power.

Polar Cruise Ship

Unlike most polar merchant ships, polar cruise vessel often is designed as low ice-class ship. Some of them only stiffen their bow simply, and some of them are modified by scientific research ships. There are two main reasons lead to this phenomenon. Firstly, polar cruise ships choose to sail in summer usually, and their routes are safer than others’. Moreover, polar environmental groups, especially Antarctic ones, have imposed strict controls on commercial shipping to protect the polar environment. For example, International Association of Antarctica Tour Operators (IAATO) divides Antarctic travel vessels into four categories depended on the number of passengers. The number of tourists is from little to large, followed by YA, C1, C2, and CR, respectively. Carrying the more tourists, received the more restrictions.

Ushuaia

Ushuaia is a cruise ship operated by Argentina’s Antarpplly Expeditions, which is shown in Fig. 6. She was built for the National Oceanic and Atmospheric Administration. She served the NOAA for 20 years under the names “Researcher” and “Malcolm Baldrige.”

CR- Prinsendam

General characteristics (shown in Fig. 7)

Length	427 ft (130 m)
Capacity	350 passengers
Crew	200

C2-Ocean Diamond

Ocean Diamond is a cruise ship operated by Quark Expeditions, which is shown in Fig. 8. She was previously named Song of Flower. Many kinds of entertainment facilities on board are ready.

General Characteristics

Tonnage: 8,282 GRT	Displacement: 3,433 DWT
Length: 124.19 m (407.4 ft)	Beam: 16.03 m (52.6 ft)
Decks: 5	Ice class: 1D
	Speed: 15.5 knots
Installed power: 2 Wichmann Engines, 7375 horsepower	

Polar Merchant Vessel, Fig. 6 Polar cruise ship Ushuaia (<https://antarply.com/>)

Polar Merchant Vessel, Fig. 7 Polar cruise ship CR- Prinsendam

Le Lyrial

With the increasing popularity of Antarctic travel in recent years, more and more shipping companies are building polar exploration cruise ships specially. These designed polar cruise ships offer more luxurious facilities on board. This makes Antarctic travel not only an adventure, but also an unparalleled enjoyment elsewhere. Le Lyrial is a new cruise ship built by Fincantieri in Ancona, Italy, as shown in Fig. 9.

50 Let Pobedy

There is a special kind of polar cruise ship whose customers are enthusiastic explorers. These explorers' pursuing is nature's pole and the limit

of human will. This kind of polar mail ship's mission tends to be held by heavy icebreakers. The Arktika grade atomic icebreaker, 50 Let Pobedy, is the most famous ship, which is shown in Fig. 10.

Since 1989 the nuclear-powered icebreakers have also been used for tourist purposes carrying passengers to the North Pole. In 2008 Quark Expeditions hired this ship to finish expeditions to the North Pole. In October 2013, the vessel carried the Olympic Flame to the North Pole, in the run-up to the 2014 Winter Olympics. In August 2017, Let Pobedy set a new record for transit time to the North Pole.

Definition

Polar offshore engineering refers to the equipment and technology to carry out scientific investigation, commercial navigation, oil and gas resources development, and tourism and leisure activities in polar regions. It is an important carrier to understand, develop, and utilize polar regions. At present, the international polar equipment is mainly divided into polar scientific equipment, polar ship equipment, polar resource development equipment, and so on.

Introduction

In general, the polar offshore engineering is such kind of engineering operated in the Arctic including exploration, development, and utilization of resources in the polar ice area, as well as the detection, protection, or recovery of the polar ocean environment.

The Significance of the Polar Offshore Engineering Development

The arctic region is rich in oil, gas, minerals, and fishery resources. With global warming and the arctic glacier melting, the arctic route has started to become the most efficient energy and materials

Polar Merchantman

- [Polar Merchant Vessel](#)

channel which connects Europe, Asia, and America. Because polar ocean environment is unique and fragile, environment protection of the polar ocean is significant for the whole human beings.

However, human activities, such as commercial activities, scientific investigation, exploitation of resources, adventure tourism, and fishing in the Arctic which is a remote area with harsh climate (low temperature, strong wind, huge waves, floating ice, etc.) and fragile environment, rely on economical, safe, and environmental polar offshore engineering equipment which are suitable for the polar environment.

The polar offshore engineering equipment are important tools and platform for us to explore, understand, protect, and exploit the polar region. The polar offshore engineering is an important subject that studies and solves the key technologies involved in the whole life cycle of research, design, construction, operation, and discarding of the polar offshore engineering equipment.

Key Technologies of Polar Offshore Engineering

- The Environment and Load of Ice in Polar Region

In extreme environment, the impact of ice floe on the structure of the polar marine equipment is significant. The perennial floating ice will cause continuous and periodic extrusion and influence on the structure of the offshore platform. The influence will cause great ice load and possibly form intense ice exciting vibration.

How to confirm the proper design ice load is a challenging technical problem. On the one hand, the work experience of the marine engineering in the polar environment is limited. On the other hand, the interaction between ice and the platform is complex, as well as the physical mechanism of the ice breakage.

In order to meet the customer's demand of ice load forecasting for marine equipment,

ABS has explored a series of new methods for numerical simulation of ice load by cooperation with universities and enterprises in recent years. For example, they use the particle-in-cell method to predict the ice load of the dispersed floating ice on the sea structure, the discrete element (DEM) method to explore the consequences of the ice load produced by the whole ice floe on the sea structure, and the traditional finite element (FEA) method to simulate the ice load with the special physical properties of the ice.

- Cold and Ice Prevention of Mechanical Systems, Electrical Systems, and Equipment

Based on the particularity of the low temperature of the polar environment and the influence of different temperature on the equipment and the function of the system at low temperature, the design and use requirements of the core equipment and system at different temperature grades are selected according to the temperature grade of the low-temperature environment.

According to the low-temperature conditions of the polar regions, the reasons for the formation of the platform ice in the low-temperature environment, the antifreezing and protection of the equipment in the open area, the indoor antifreeze, and the deicing of the platform are studied to ensure the safety of the polar operating platform and the operation of the equipment.

- Development and Application of Low-Temperature Materials

Low temperature is another major challenge for polar offshore operations. Extreme low temperature will not only test the physical condition of the staff on the marine equipment but also have a great impact on the structure, equipment, and materials of the marine equipment. As we acknowledge, winter of the Arctic region usually starts from November to April next year. The average temperature in January is -20°C to -40°C , and the average temperature in the warmest month is only -8°C in August.

The toughness of ordinary materials is decreased in the low-temperature environment,

and the possibility of brittle failure is greatly increased. The brittle failure is difficult to find out in the early stage, so it is more likely to cause serious consequences, especially in the extreme low-temperature sea conditions of the polar region. The safety problems such as material fracture, pipe and valve plugging, control system failure, and so on should be paid more attention. Therefore, research and development of low-temperature-resistant materials will become the focus of future development.

- Communication and Navigation Technology in Polar Regions

The global maritime distress and safety system (GMDSS) has been listed as a special A4 sea area because the polar regions cannot be actively covered by INMARSAT's satellites due to its far distance. In addition, the electromagnetic environment of the polar region is more complex than that of the Earth's magnetic field. Moreover, the development of polar resources depends on the development of underwater communication under ice, which is also a key technology for polar marine engineering equipment.

- Ocean Environmental Protection, Monitoring Technology, and Standards in Polar Region

The problem of polar environmental protection is a serious problem. In order to protect the fragile ecological environment in the polar region and reduce the chain reaction caused by the development of the polar ocean as far as possible, the International Maritime Organization and other organizations have established the "polar rules" and formally entered into force in January 1, 2017. In spite of this, some scholars believe that the existing pollution prevention measures in the rules are not sufficient to protect the special ecological environment of the polar region. In order to further improve the pollution prevention measures of the rules, the specific provisions and proposals are deeply analyzed with the method of fish bone map analysis and comparative analysis, and the corresponding revisions are put forward suggestions on this basis.

Main Equipment of Polar Offshore Engineering

In the polar, the temperature is very low, and the climatic condition is very poor; polar offshore engineering development is facing great challenges. The main offshore engineering equipment currently operating in the polar field includes drilling platforms, FPSOs, drilling vessels, supply vessels, subsea production facilities, and so on.

1. Polar Icebreaker

At present, the countries with polar icebreakers in the world are mainly distributed in the near polar region, including Russia, Finland, Canada, the United States, China, and so on. Among them, Russia is the country with the most polar icebreakers.

- "NORTH" Level Nuclear-Powered Icebreaker (22220 Type)

For the icebreaker as shown in Fig. 1, the length is 170.3 m, the width is 34 m, and the draft is 10.5 m. It is equipped with two new generations of RTM-200 nuclear reactors. Each reactor has a power of 170 MW and can break 3 m of ice. The icebreaker joined the Russian nuclear fleet in December 2017. It can travel in the shallow waters of the Arctic Ocean or in the deep waters and can guarantee the passage of ships with a load of 100,000 tons.

2. Polar Drilling Equipment

At present, there are relatively few drilling platforms specially aimed at the polar operations; those that have been put into use are from Norway and Russia, and some of the platforms are made in China. The details are as follows in Fig. 2:

- CS50

CS50 is a semisubmersible rig which is registered in Russian Maritime Register of Shipping. For the operation areas in the Barents Sea and in the Kara Sea, drift ice on the sea may occasionally occur. The SMODU shall be designed to operate in occasional first-year drifting thin ice. However, the SMODU shall not have any ice-class notation. The length of pontoon

Polar Offshore Engineering,

Fig. 1 “50th anniversary of victory.” (Image from the network: http://www.sohu.com/a/190672530_99968045)

Polar Offshore Engineering,

Fig. 2 Russian offshore – CS50. (Courtesy of Yantai CIMC Raffles Offshore Ltd)

is 118.56 m. The breadth of pontoon is 17.20 m. The spacing of pontoon is 58.00 m. The length of deck is 84.48 m. The breadth of deck is 72.72 m.

- North Dragon

GM4D North dragon is a semisubmersible drilling rig (the unit) built by YANTAI CIMC Raffles. The rig is equipped and suitable for year-round operations worldwide, inclusive operation on Norwegian Continental Shelf (NCS). Therefore, the design process and

the technical facilities of the unit shall comply with relevant Norwegian shelf rules (PSA Regulation). The pontoon length of the rig is 106.75 m. The breadth of pontoons is 16.20 m. The length of deck is 88.15 m. The breadth of deck is 73.10 m. The height from the bottom of pontoon to double bottom of deck is 42 m, as shown in Fig. 3.

- Cat-I Polar Drilling Ship

Norwegian Inocean's Cat-I drilling ship concept design for Statoil, based on

Polar Offshore Engineering,

Fig. 3 GM4D – North Dragon. (Courtesy of Yantai CIMC Raffles Offshore Ltd)

Polar Offshore Engineering, Fig. 4 Cat-I Polar Drilling Ship. (Image from the network: <http://www.offshorelm.com/cn/>)

its INO-80 drilling ship, added cold-resistant devices, etc., which is designed to be suitable for the work in the polar area, which minimizes the impact on the environment and can maximize the concern of the health, safety, and environmental management system (HSE), as shown in Fig. 4.

The ship length is 232 m, the width is 40 m, and the depth is 19 m. The working displacement is 89,800 tons, and the effective load is 22,400 tons. The hull of the ship is reinforced for passing through the ice zone. It can resist the 16-m ice ridge when it is positioned by dynamics and can resist the 8-m underwater ice when anchoring.

Polar Offshore Engineering,

Fig. 5 “Sevan 1000”

FPSO 平 (https://www.eniday.com/en/technology_en/goliat-norway-offshore-oil-production/)

- “Sevan 1000” FPSO

The “Sevan 1000” FPSO was designed by Sevan Marine in 2013. The FPSO is specifically designed for Eni’s Goliat oil field in the Barents Sea in the northern Arctic of northern Norway. The climate is cold, and there is a need for better performance FPSO. The equipment was built by Hyundai Ulsan Shipyard in Korea and completed in 2015, as shown in Fig. 5.

Compared with conventional ship types, the cylindrical structure can better withstand the ice drift pressure in different drift directions while avoiding the drift ice floes causing damage to the semisubmersible hull. The cylindrical platform lower space can be used to store more oil than a typical platform unit.

Polar Offshore Engineering Development Trend

At present, most countries are actively participated in the establishment of international polar

rules and accelerate the study of polar rules and related supporting equipment.

Independent research and development of heavy icebreakers, polar drilling equipment, polar scientific research equipment, polar expedition travel equipment, and related technologies to meet the strategic needs of polar seas and the construction of ice pool laboratory, low-temperature material laboratory, low-temperature electromechanical system verification experiment, the laboratory verification conditions, and the actual ship verification system are the key development directions of the major base equipment strength countries.

In addition, we should energetically cultivate the experienced polar ship handling and management personnel, realize the safe and reliable operation of the equipment in the polar sea area, fully verify the guidelines for the operation of the polar navigation, and continue to improve.

At the same time, we should speed up the development of meteorological and insurance services in our Arctic waterway so that the polar region can truly become a “treasure trough” and a “golden waterway.”

F_b	Maximum backward bending load
F_f	Maximum forward bending load
α_A	Apparent angle of attack for the blade section

Introduction

Ice-going vessels operate in the ice conditions that present various challenges to the propulsion system performance. Compared with conventional propulsion, the focus and difficulty of polar propulsion are that the conventional hydrodynamic performance, noise, cavitation, and excitation force of the propeller become more complicated due to the addition of ice. What is

more complicated is the propeller will have a great chance to be in contact with the ice body directly during the ship navigation in the ice area, which makes the propeller suffer ice load directly. This will bring new challenges to the strength verification and the design work of the propeller. Therefore, polar propulsion is not simply an extension of a single discipline. It is a comprehensive science with direct value of engineering application. At present, the research focus of polar propulsion mainly contains the measurement and prediction work of propeller load, the propeller strength verification, and the design work.

Polar Propulsion Requirements and Selection

Icebreakers are typically meant to operate in more severe ice conditions than normal ice-going vessels, which means that strength and thrust requirements for the propulsion system need even more special consideration. Operative situations that require good maneuverability include assisting other ships, making ships free from ice, changing direction (astern), operating in narrow ports, and breaking out of channels. In addition to the raw power, some of these operations require precision and good controllability of both bow and stern of the vessel at various speeds. If the icebreaker is specified to have dynamic positioning capabilities, requirements for propulsion system are even more difficult to be satisfied with traditional shaftline and rudder arrangements.

Redundancy requirements of higher DP classes result in a need of multiple transversal or azimuthing thrusters at both ends of the ship. In such cases, azimuthing thruster propulsion is highly efficient as it can be used to reduce the total number of the thrusters. The axis of the Azipod propeller is vertical axis, and the propeller can rotate 360° around the axis, and it can obtain the maximum thrust in any direction. It can make the ship rotate in place, move laterally, retreat swiftly, and perform special operations such as steering in the low-speed range. Azipod propeller is divided into the Z-Azipod propeller and podded propulsion system. The structures of the two

propellers are different, but their hydrodynamic performance is similar. For the current widely favored bi-directional dynamic icebreaking, selecting the Azipod propulsion would bring too many benefits. The azimuth thruster eliminates the structure of rudder, tail, and stern tube. It also would simplify the ship stern shape and reduce hull resistance. Besides, it would not be neglected that the maneuverability of polar ship would be outstanding by using Azipod propeller. However, it would be not neglected that adjustable-pitch propellers would be another good choice for polar propulsion. Almost all of the propulsion of icebreakers built and rebuilt in the last two decades apply adjustable-pitch propellers or azimuth thrusters (including Rolls-Royce propellers, Azipod propellers, Schottel propellers, and Steerprop azimuth propellers). Adjustable-pitch propellers can use the operating mechanism in the hub to rotate the blades and change the pitch distribution of the blades, which will help to make the main engine power being fully absorbed under various operating conditions. It can not only improve the propeller performance but also reduce fuel consumption and improve economic efficiency. One of the advantages of adjustable-pitch propellers in the ice area is that they could produce more great thrust. This point is of great significance in the current situation of high energy costs. In addition, the effect of free ice in the propeller wake can be eliminated by adjusting the pitch. However, as the design of the propulsion system for the vessels in ice areas, the adjustable-pitch propeller and the Azipod propulsion device both have their own advantages and disadvantages. A new idea that the propulsion device is a Z-type transmission propulsion system has additional conduit with adjustable blades. The advantage is that the conduit has a protective effect on both the blade and the hub and improves the reliability of the propeller. This is particularly important for special propellers that are difficult to maintain after being damaged. The adjustable pitch and the overall rotation of the propeller around the shaft can greatly improve maneuverability of the vessels in ice areas and the efficiency of icebreaking. Adjustable-pitch blades can not

Polar Propulsion, Fig. 1 Azipod propeller and ducted propeller. (Referenced website: <http://www.engineeringsociety.co.uk/pod.html>)

only increase the propulsion efficiency in open water areas and the ability to break thick ice but also increase the thrust of the blades during icebreaking operations. The adjustable-pitch propellers and the Azipod propulsion system have been the research direction of icebreakers' propulsion devices in recent years. From the side, this data statistic also verifies the applicability and rationality of the application of adjustable-pitch propellers and Azipod propulsion system to the icebreaker. Figure 1 shows the Azipod propeller and ducted propeller.

P

Propeller Load

The polar propeller would be subjected to the following three types of loads: inseparable hydrodynamic load, separable hydrodynamic load, and ice load. Separable hydrodynamic load refers to the hydrodynamic load in open water conditions. Inseparable hydrodynamic load refers to the hydrodynamic load considering the influence of ice on the disturbance of the flow field, generally including the blocking effect, proximity effect, and cavitation effect. The ice load is caused by direct physical contact between ice and propeller blade and can generally be divided into two kinds: ice milling load and ice impact load. The division is based on the contact model and the contacting ice block size.

Hydrodynamic Load

At present, researchers study hydrodynamic loads mainly through the model tests and numerical predictions. People choose the model test as the main test style, and this is because compared with the full-scale test, model test has the advantages of less finical and labor cost as well as less demand for experimental conditions. And the shortcomings of model test are the uncertainty of similarity law between model test and real working condition. Besides, the selection of sea ice material in the model test is also the key to the success of the test. At present, there are frozen ice models as well as nonfrozen sea ice models made from other materials such as nonfrozen breakable synthetic materials.

Many scholars around the world have carried out research work on the prediction of propeller hydrodynamic load under ice loading. Among them, Yamaguchi (1993) proposed a lifting surface method to predict the propeller performance considering the interference of flow from ice. Bose (1996) used a three-dimensional unsteady surface element method to predict the performance of a propeller under the conditions of blocking flow. Doucet et al. (1998) predicted and analyzed the fluctuation of axial force of several large skew ice class propellers with the help of panel method PROPELLA. Liu Pengfei et al. (2002) simulated blocking flow conditions with three different ice shapes using the panel method program PROPELLER. Numerical results show that the blade load during the blockage is close to

the experimental results. On this basis, they have made a series of further studies on the hydrodynamic load prediction of propeller surface under the interaction between ice and flow in the following years. They improved the Kutta conditions of the unsteady program and carried out the design of heavy load ice class propeller based on improved panel method (2010). Previous researches on the inseparable hydrodynamic load were mostly based on potential flow theory. Therefore, the fluid viscous effects and boundary layer problems on ice and propeller could not be analyzed. In fact, these factors would show great influence on the performance of propeller. Wang (2013–2018) used the viscous flow theory and CFD overlap grid technology to numerically predict the propeller hydrodynamic performance and induced excitation force during the ice-propeller interaction process and developed the numerical prediction method of the induced excitation force and cavitation excitation force under ice blocking conditions and ice progressive conditions (Fig. 2).

Polar propellers are generally under heavy load conditions during icebreaking. It is difficult to avoid cavitation on the surface of the propeller, and the phenomenon of cavitation tends to aggravate the vibration and noise of the propeller, which in turn affects the hydrodynamic performance and strength of the propeller. The propeller-ice-flow interaction process is very complex. In order to simulate the ice-propeller milling and impact conditions, a large number of model tests have been carried out in the ice tank.

Polar Propulsion, Fig. 2 Propeller-ice milling process in cavitation tunnel (Wu et al. 2018)

However, due to the fact that atmospheric pressure cannot be scaled in the ice pool, the determination of the hydrodynamic load in the ice tank is often performed under the assumption that there is no cavitation on the propeller surface. In order to study the problem of cavitation in ice-propeller interactions, Lindroos and Björkestam (1986) simulated the propeller cavitation under the ice-propeller interaction in a cavitation tank for the first time. They placed a flat plate in front of the propeller to induce cavitation. The results showed that the blocking flow will make the propeller vibration and cavitation more serious, which in turn will increase the thrust and torque of the propeller. His study pointed out the importance of the study of the cavitation phenomenon. Sampson (2007) conducted propeller cavitation model tests in Emerson's cavitation tunnel during the period. The results of the study showed that the cavitation during propeller-ice interaction has a great influence on the strength and performance of the propeller. Cavitation will influence the thrust and torque of the propeller, causing severe vibration and noise, and cause fatigue damage to the propeller blade.

Ice Load

The ice load is caused by the direct contact between ice and propeller. It accounts for the most important part of the total load on the propeller. The study shows that the ice load is more than one order of magnitude larger than the hydrodynamic load. The contact loads are usually separated into milling-type or impact-type loads.

The difference between the two is not very clear. The load has often been classified as a milling load if the contact lasts more than one revolution, which means the same blade hits the ice block more than twice. In this work, the contact is always considered to be of the milling type when the leading edge of the blade comes into contact with ice, even if the ice block is small and the duration is not enough for a blade to pass. If the blade and ice block velocity geometry is such that the block hits the blade at the back or face side, without leading edge contact, the contact load is classified as an impact load. According to the propeller-ice contact model proposed by Kinnunen (2015), the angle of attack is accordingly one of the main parameters in contact load calculations (Fig. 3). The contact geometry between an ice block and the blade back side depends on the angle of attack as shown in Fig. 5. It is, however, not well-known in practice, since the actual wake factor at the disk level in ice conditions is not known. The propeller can accelerate the ice block before contact, or the ice block can be supported by other ice blocks. Therefore, an apparent angle of attack is used to indicate the contact geometry in this work, assuming the ice block enters into contact at the ship speed, V_s , as shown in Fig. 4. α_A is the apparent angle of attack for the blade section, V_s is the ship speed, n is the propeller speed, r is the radius of the section, β_r is the angle of advance of the section, ϕ_r is the pitch angle of the section.

At present, the research on the ice load is mainly obtained by numerical prediction and

model test. Sampson carried out a series of ice cutting tests in air test platform and measured the ice load of propeller under ice cutting condition separately. With the development of computing ability, the use of commercial software or self-programming to predict blade ice load has become a mainstream. Compared with model tests, numerical prediction has the advantages of simple calculation, free working conditions, and low investment. However, how to simulate ice material and the fracture process of ice materials during milling process has become the main constraint to the application of numerical prediction. Among them, Hu and Xia (2013) built the propeller-ice contact model based on the ANSYS/LS-DYNA platform. The sea ice was simulated by SPH method. And the finite element method is used to solve the structural deformation of the blade under ice load. In the same year, the structural dynamic response of propeller blade under different milling areas, advance speeds, and collision angles were studied and analyzed through this numerical model. To handle a large number of discontinuous problems happening in the ice-propeller milling process, Ye et al. (2017) introduced meshless method peridynamics and established ice-propeller numerical model. He carried out many prediction calculations to ice impact conditions and ice milling conditions and obtained the variation regularity of the blade ice load with external conditions, as shown in the following picture.

Mixing Load

The ice-water mixing load of propeller in ice areas has always been the focus and difficulty in the research. At present, the most effective research methods are model test measurements. Among them, Wang et al. (2005) carried out model test of Azipod propeller milling ice in IOT's tank and obtained valuable data of the mixing loads as Fig. 6 shows. These graphs except for the carriage speed are plotted over a 1-s interval, the 65th to 66th seconds. In the time series records for the forces and moment, five peaks can be seen because the propeller rotational speed was 5 rps. The carriage speed for the duration of the 65th and 66th seconds was 0.5 m/s. Wang et al. (2007) installed a 6-degree-of-freedom mechanical sensing device at the root of the main blade and successfully measured the ice-fluid mixed load of the blade. There are no well-developed numerical prediction due to the complexity mechanism of fluid-solid coupling. Wang et al. (2017) try to establish the numerical model with PD-FEM-SPH coupling method, but the meshless method makes the calculations work too large being performed. So establishing a numerical method to this kind of problem would be very innovative and of engineering practicality.

Polar Propulsion Strength

The strength of polar propulsion is very essential. In order to check the propeller strength more

Polar Propulsion, Fig. 5 Six degrees of loads measured in model test conducted in IOT ice pool (Wang et al. 2005)

effectively, many classification societies have formulated special standards for the polar propeller strength and add them into the ice class rules separately. The International Association of Classification Societies (IACS) had collated and arranged the existing regulations to ensure the safe navigation of ships in the ice areas and formulated the IACS ice grade specification in 2008. At present, most of the ice class specifications around the world are very similar to the specifications put forward by IACS. The specification does not only contain the demand for the strength checking under ice load but also provide the requirements for the material properties of propeller. The load given in the IACS ice class rules is only applicable to the propeller, also defined as the maximum load that the propeller is expected to sustain during the life cycle.

The load given should be recommended as the total load including hydrodynamic load and ice load. For conventional propeller blades, the design load calculation method introduced by the IACS specification is given by Eq. 1 through Eq. 6.

F_b is defined as the maximum backward bending load on the blade during the ship life cycle, D is the propeller diameter, n is the propeller speed, EAR is the disc area ratio, Z is the number of blades, H_{ice} is the ice thickness, D_{limit} is the ice thickness index, and S_{ice} is the ice intensity index:

$$D < D_{limit}$$

$$F_b = -27S_{ice}(nD)^{0.7} \left(\frac{EAR}{Z} \right)^{0.3} D^2 \text{ kN} \quad (1)$$

$$D \geq D_{limit},$$

$$F_b = -23S_{ice}(nD)^{0.7} \left(\frac{EAR}{Z} \right)^{0.3} H_{ice}^{1.4} \cdot D \text{ kN} \quad (2)$$

$$D_{limit} = 0.85 \cdot H_{ice}^{1.4} \quad (3)$$

F_f is defined as the maximum forward bending load on the blade during the ship life cycle:
